Painting the skin of mice with this extract three times weekly for a period of 1 year produced no neoplastic changes The addition of croton oil to the benzene extract produced some thickening and ulceration of the skin, but no carcinomas A group of mice were then given ultraviolet radiation to both ears, and the right ears were painted with the extract, however, the results showed no augmenting effect of the skin extracts, and carcinomas developed on both ears equally Subcutaneous injections of the extract into mice produced no neoplasms, and similar results were obtained by the implantation of whole keratoses The patients showed no difference in the two sides of their faces as the result of washing with benzene, since carcinomas developed with equal frequency on the washed and unwashed sides

These findings are believed to be evidence in favor of the hypothesis that the carcinogenic influence of ultraviolet rays is exerted by a direct effect upon the cell constituent responsible for neoplastic change rather than the formation of a carcinogenic chemical

ROBERT MAYO TENERY, M D

The Cancer Problem C P RHOADS *J Urol*, Balt, 1948, 60 797

The author states that outstanding developments in the induction and control of cancer in man have come from the study of the bladder, prostate, and adrenal glands

The bladder cancer which follows exposure to B-naphthylamine is the only instance of the production of a malignant tumor in man by a pure chemical compound of known composition

Its induction led, furthermore, to the demonstration that certain forms of experimental cancer, due

to the administration of azo dyes to animals fed inadequate diets, can be prevented by specific food constituents

The second great contribution of urology to cancer was a procedure for the potential control of human neoplasms From a mass of standard experimental work, it was more than obvious that the prostate, like the breast, requires a hormone (male in this case) not only for its development but for its very existence

The author points out that castration, at least temporarily, causes cessation of growth of the neoplastic cells

The author then goes on to discuss the history of tar as a cause of cancer and how British workers isolated pure crystals from tar that proved to be cancer-producing Shortly afterward the molecules of pure female and male hormone were described

It was obvious that the cancer-producing substance from tar and the steroid sex hormones had some similarity

The chemical relationship between carcinogen and steroid hormone suggested, of course, the most important concept since the observation of Pott This was that cancer in man may be due perhaps to a manufacturing mistake by the body in which there is formed a carcinogen instead of a natural hormone

Two very well established, but oftentimes forgotten, clinical facts show adequately the participation of some systemic generalized factor in the cause of cancer The first of these is the rather frequent occurrence of multiple primary cancers Every student who has investigated this subject has provided confirmatory information A recent and important study is that of Warren and Ehrenreich, who showed that at autopsy 6.8 per cent of their patients dying of cancer had multiple primary growths, and these were not the simple multiple primaries involved in the tiny, comparatively benign, basal-celled epitheliomas of the skin

Rather more important in support of this thesis of the systemic or biochemical metabolic origin of cancer is the astonishing tendency of cancer of the same organ to occur coincidentally in single-ovum twins The proof that this is truly a matter of the similar genes of the monozygotic twins is at hand because of the fact that of 13 pairs of double-ovum twins with tumors of one, only 2 presented involvement of the second twin Macklin's series of similar and dissimilar tumors in twins, both of whom were affected with tumors, is particularly interesting Among the monozygotic twins, there were 22 similar tumors and only 1 dissimilar tumor, whereas among the dizygotic twins, there were only 6 similar and 7 dissimilar tumors

Support for the systemic origin of cancer is found in seven other factors

1 The tendency of testicular tumors to occur in cryptorchids, and their treatment by pituitary extracts

2 The occurrence of uterine cancer with granulosa-cell tumors of the ovary

3 The experimental production of adrenal tumors by the castration of certain strains of very young animals and by the intrasplenic transplantation of genital tissue

4 The effect of biologically active steroids on cancer of the prostate gland in man and of the breast in women is well known

5 The administration of estradiol to experimental animals is capable of producing regularly no less than five different types of malignant neoplasms

6 There is a profound peak for many forms of cancer at the age of the menarche and menopause, and sex-linked cancer is enormously common, so much so as to make reasonable the statement that the malignant neoplasm is one of the most fundamental importance

7 The geographical incidence of cancer provides further confirmatory evidence for the etiologic role of a general disorder

The author then discusses the search for endocrine substance in the urine of individuals with cancer

He notes certain compounds are absent in individuals with cancer and other substances not found in normal urine are found in the urine of individuals with specific types of cancer. One substance in particular " Δ^9 Etiiocholenolone" is of particular interest

He presents an interesting case in which the urine was studied for 2 years prior to discovery of the cancer and for several years after its excision

Paget's disease is a condition peculiarly liable to be due to, or associated with, an abnormality of steroid hormone metabolism, because of the important role played by these hormones in bone growth and calcification

For these reasons an ideal patient with Paget's disease was hospitalized for a long period and patterns of urinary steroid excretion were prepared. An extraordinary abnormality was apparent. One wholly new steroid, of a type never found in any other urine, was present

The author states that they have found that in patients with cancer there is adequate evidence indicating a disturbed manufacture of steroid hormones, a fact which is significant but not specific for the disorder. He suggests that before cancer is obvious a similar disturbance of hormone manufacture is present. He has evidence that in conditions which are fully accepted as precancerous (notably Paget's disease of bone) abnormalities of steroid hormone excretion are present, a fact which warrants the belief that this condition is endocrinologic in origin

"Talc is a Dangerous Agent in its present use as a Surgical Glove Lubricant"¹

SAFE SUBSTITUTE NOW
AVAILABLE AT COST OF
ONLY 2¢ PER OPERATION

Postoperative adhesions caused by glove powder have long been a serious concern of surgeons and operating room assistants

All published studies agree that talc as a glove lubricant is unsafe. Animal experiments have shown the dangerous complications that follow talc implantation

* * *

EFFECTS IN TISSUE

Talc consists chiefly of magnesium silicate. It causes granulomatous reactions in tissue, resulting in intra-abdominal adhesions, persistent sinus formation, or nodules in the wound

* * *

"Implantation of glove powder may occur from unwashed gloves, perforations in gloves, spill on to sponges, instruments, and suture material, and by the air borne route"¹

* * *

SERIOUS COMPLICATIONS

"The frequency of such contamination is attested by the increasing number of case reports of serious complications due to talc. Animal experiments show that the granulomatous reaction can be regularly produced in the peritoneum, pleura, pericardium, muscle, joint, nerve and tendon"¹

FOREIGN BODY REACTION

German^{2,3} found intra-abdominal granulomata which he proved came from foreign body reaction to talc in 40 out of 50 unselected patients subjected to a second laparotomy

* * *

Seelig^{4,5} repeatedly demonstrated the danger of talc in mice, which are notably resistant to the production of adhesions, by injecting 2cc of a 5% saline suspension of the powder intra-peritoneally, and has stated that "the average surgeon cannot possibly perform this experiment and ever afterward face talcum powder with equanimity"

* * *

REPLACEMENT

As a replacement for talc, a wholly safe and efficient dusting powder is now available. This new powder, called Bio-Sorb, is a mixture of amylose and amylopectin, derived from corn starch, with a small amount of magnesium oxide added. It is treated physically and chemically to assure good lubrication after sterilizing

* * *

COMPATIBLE WITH TISSUE

Bio-Sorb is compatible with body tissues and is rapidly absorbed. It does not injure rubber gloves. It fits regular O.R.

technics. Costs less than 2 cents per operation. Bio-Sorb has been used over two years in several hundred hospitals. Complete literature mailed on request.

* * *

SAFETY CONFIRMED

The findings of Lee and Lehman⁶ that Bio-Sorb is safe have been confirmed by Lindenmuth⁷ and MacQuiddy⁸. Postlethwait et al¹ concluded that "talc is a dangerous agent in its present use as a surgical glove lubricant," and stated that "a modified starch powder (Bio-Sorb) which is absorbed with little or no reaction is again suggested as a satisfactory substitute for talc"

EXPERIMENTAL ASCITES

Effects of Sodium Chloride and Protein Intake on Protein Metabolism of Dogs with Constricted Inferior Vena Cava

F W McKEE, M D, J A SCHILLING, M D, G H TISHKOFF, B S, and
R E HYATT, A B, Rochester, New York

ASCITES may be produced experimentally in dogs by constricting the inferior vena cava above the diaphragm, with an aluminum band. The protein content and the amount of ascitic fluid formed in these animals may be predictably influenced by the protein or sodium chloride intake. The fluid content of the peritoneal cavity shares to a greater or lesser degree in the expansion and contraction of the interstitial fluid volume, though in an altered way when abnormal hydrostatic, osmotic, or permeability factors exist in the portal system. The removal of ascitic fluid is essentially an internal plasmapheresis in that it represents a removal of protein from the circulating plasma and tissue protein stores. Also the ascitic fluid protein may enter into the dynamic protein equilibrium of the body. The purpose of this paper is to report further observations (47) on our experimental animals, to describe the surgical technique, and to review the pertinent literature.

Ascites has been noted clinically for many centuries. The literature is replete with case reports and treatments of this symptom which has many causes. These causes may be listed

under several headings: cardiovascular, hepatic, renal, inflammatory, neoplastic, nutritional, and idiopathic. Bright in 1839, classified the causes of ascites and effusions very completely with descriptive case reports. The lucid descriptions of Flint (28) in 1863, have hardly been surpassed in recent literature. In reviewing the reports of surgical and medical methods of treatment of ascites little may be found regarding the actual nature of this symptom. Most of these reports are of historic interest only. Medically such drugs and methods as the mercurials, iodine, strychnine, quinine, adrenalin, camphor, pilocarpin, tobacco, digitalis, intraperitoneal alcohol, ether, sclerosing agents, and claret, chloroform, African honey, oxygen, oil of copaiba, electrical stimulation, compression, decompression, etc. have been recorded with beneficial results. Little attention was given to exact diagnoses and most of the cures reported were probably due to bed rest and improved nutrition.

Surgically symptomatic relief from intractable ascites of one cause or another has been attempted in various ways. Most frequently repeated paracenteses (29) have been carried out. Second, attempts have been made to devise a more permanent form of drainage of ascitic fluid from the peritoneal cavity sub-

From the Departments of Pathology and Surgery, The University of Rochester School of Medicine and Dentistry.

cutaneous buttons of rubber or glass into the peritoneal cavity (54, 63, 20, 42), a subcutaneous tunnel of omentum (55), anastomosis of the peritoneum to the saphenous veins (5) or renal pelvis (27), the use of "lymphatic lined" tubes from silk sutures (62, 46), parafined veins (4), cannulas to the external surface of the abdomen with a detachable cap (17), subcutaneous dermic fistulas (40), and finally resection of the parietal peritoneum (52) has been attempted. A third approach has been to attempt to improve the collateral circulation of the hypertensive portal system. Methods in this group include the Talma (62) Drummond-Morrison (23) omentopexy, anastomoses of sigmoidal to saphenous veins (3), splenic to renal veins (7), superior mesenteric to vena cava (14, 51), and finally the Eck fistula (24) used by Krestowsky, Rosenstein, and most recently by Whipple (65) and Blake-more (6). A fourth surgical method has been laparotomy in females with unexplained ascites and excision of pelvic tumors if present (2). These cases of ascites associated with pelvic tumors comprise a small but very interesting group. When associated with a hydrothorax both effusions may be cured by excision of the ovarian fibroma. This method was first described and reported by Cabot from the Massachusetts General Hospital in Boston though recently it has been emphasized by Meigs and many others in the last decade. The etiological factors of this bizarre syndrome are unknown. Lastly splenectomy (65) or enterectomy (31) has been employed to reduce the quantity of portal blood flow to the liver in cases of portal obstruction where hematemesis rather than ascites often was the main symptom. It is not the purpose of this communication to discuss the merits and results of the above various forms of therapy. These may be obtained in the above references and the following reviews (18, 36, 65).

Experimental methods for production of ascites are few. Bollman (8) ligated the common bile duct in dogs. Ascites regularly occurred and increased after a high protein diet. Massive saline infusions are known to increase the peritoneal fluid content in moderate amounts (19). Wangenstein mimicked ascites by introduction of tap water under pressure.

The most reliable method has been the constriction of the inferior vena cava above the liver. This procedure was carried out in conjunction with other work by Whipple and Sperry (66) through a transthoracic approach by use of sutures to constrict the vena cava above the diaphragm. Bolton (10) constricted the pericardium around the right auricle by sutures and was able to cause ascites in cats. In later years (11, 12, 13) he used ligatures and metal bands around the vena cava above the liver. Zimmerman and Hillsman used an aluminum band successfully in 1930. Kershner and associates, in 1946, in multiple stages ligated the inferior vena cava above the liver with ligatures. The mortality rate among their animals was prohibitive, however. Bollman (9) has recently employed cellophane bands above the liver around the inferior vena cava with production of ascites after an unpredictable interval of fibrosis about the vessel. Below the liver, cellophane bands failed to produce ascites, when placed around the portal vein. Ascites could be produced at a later date in these animals by constricting the vena cava above the liver.

Ascitic fluid has also been investigated extensively as a transudate under clinical and experimental conditions (33). This subject has been recently reviewed by Armstrong, Patek and his associates, Mankin and Lowell, Gibson, and Peters. Their experimental observations indicated that the flow of water between plasma and ascitic fluid was not entirely in accord with Starling's original hypothesis. Ascitic fluid formation was not determined solely by the level of plasma oncotic pressure, i.e., plasma albumin. They suggested other factors, namely, changes in permeability in the portal vascular bed and in sodium chloride and water metabolism. The importance of the sodium ion in the production of edema is now generally recognized though it was first suggested by Herringham and Hadfield, in 1905. The recent experimental work of Rall, Farnsworth, Merrill, Luetscher and Hall (44), Eder and associates, and Fox, in addition to that of the aforementioned investigators, may be referred to for detailed discussions regarding the mechanism of ascitic fluid formation, the relation of the sodium ion, and the

Fig 1 Anatomical relations of inferior vena cava in the chest showing site of constricting band

role of the underlying pathological process. Specific mention should be made of the experimental findings of Grindlay and his associates. They were able to demonstrate that there was a marked increase in hepatic lymph flow following chronic obstruction of the inferior vena cava above the liver with cellophane bands. The liver lymphatics became greatly dilated and enlarged. The lymphatics of the spleen and mesentery were not engorged. Finally mention should be made of the use of ascitic fluid as a blood substitute (21, 22, 50). This is of interest particularly because of the similarity between the protein composition of ascitic fluid and plasma (43) (Fig 2).

METHODS

Normal healthy dogs, averaging 8 to 10 kilograms, were used in these experiments. The animals had been in the animal house under routine care a number of months before use and were fed a kennel diet of hospital

scraps mixed with prepared dog food. The animals were free of distemper and any discernible intestinal parasitic infestation. Prior to operation the animals were placed in metabolism cages in the laboratory and constantly observed. Here nitrogen balance studies were carried out. Blood proteins, weight, fluid intake and urine output were recorded in this control period. Fibrinogen levels and sodium chloride studies were made in some animals. The animals were fasted 24 hours before operation, and then anesthetized with intravenous veterinary nembutal. The initial dose averaged 65 milligrams per 24 kilograms of body weight or 1 gram per 5 pounds. The drug was injected slowly at first to determine any sensitivity, then fairly rapidly to within 1 cubic centimeter or 65 milligrams of the required dose. The remainder of the drug was then injected slowly depending on the animal's reaction. A lateral leg vein was usually used with the animal in a comfortable lying

Fig 2 Electrophoretic patterns of plasma, a, and ascitic fluid, b, protein of Dog 42-893 drawn on consecutive days

position on the table and an assistant patting and talking to the animal. This has been very effective in allaying apprehension and reduces the amount of nembutal necessary. The animal was then gently placed on his left side and the right chest was clipped and shaved. A continuous infusion of normal saline was started in one of the accessible hind leg veins. This served to maintain the animal's fluid balance during the operation and also to provide a readily available route for repeated injections of small amounts of nembutal when necessary to support a satisfactory plane of surgical anesthesia. An intratracheal tube was then introduced and the balloon distended to make a closed system. A Foley catheter served very well for this purpose. The right chest was then cleansed with soap, water, alcohol, and zephiran, and draped. An incision was made over the 6th or 7th interspace from the costochondral junction of the ribs anteriorly to their posterior angle. The skin, subcutaneous tissue, and external fascia were divided. The latissimus dorsi was cut transversely. The in-

terdigitations of the serratus anterior were separated and the intercostal muscles cut, with exposure of the pleura. At this point the intratracheal tube was connected to a positive, alternating oxygen pressure device of Gunkler. The pleura was incised and the lower lobes of the right lung allowed to collapse. A self-retaining retractor was inserted which gave adequate exposure without rib resection. They were gently moved upward and lateralward, covered with a moist sponge, and the inferior vena cava was exposed as it traversed the pleural cavity from right auricle to diaphragm. This is shown in Figure 1. The vein was easily freed from its pleural reflections and the phrenic nerve, which was intimately associated with the vein, was readily dissected away. The diameter of the vein was accurately measured with a caliper and a malleable aluminum band 1 centimeter in width was placed around the inferior vena cava midway between the heart and diaphragm. The band was then constricted in a circular fashion so that the resulting lumen of the vein was one-half of its original

diameter. The lobes of the lung were then replaced and allowed to re-expand. The wound edges were approximated by two No. 2 chromic catgut sutures around the rib above and below the incision. The remaining layers were closed with continuous or interrupted No. 000 silk sutures. Interrupted No. 00 plain catgut continuous subcuticular suture was then placed in the dermis. If interrupted silk sutures are used for the skin instead, a jacket should be placed on the animal. Ordinarily, if the animal can lick the wound, healing is better without a dressing or covering of any sort. Strict hemostasis and aseptic technique were observed throughout. When the pleura was completely closed, the positive pressure was discontinued, and the balloon of the intratracheal catheter released, allowing the dog to take over his own respirations. Due to the mobility of the dog's mediastinum this was the only critical period in the anesthesia. However, if care is taken at this stage to avoid a sucking wound and pneumothorax with collapse of the lung after re-expansion has been carried out, no difficulty will ensue. The animal was then placed in his cage and observed. Recovery was usually prompt. Kennel diet and water were allowed *ad libitum* the next day. The animal was then given a rest period of observation of 3 weeks or more on a high protein, low salt diet until the wound was completely healed and all outward effects of the operation were over. Ascitic fluid accumulation was detected within a few days in each of the dogs studied.

Determination of blood total protein and albumin, ascitic fluid total protein and nitrogen, and urinary nitrogen were made throughout the experiment at semi-weekly intervals, in order to study variations in the levels of the plasma and ascitic fluid protein constituents, and to establish the course of the nitrogen balance under the varied experimental conditions. The plasma and ascitic fluid total protein levels, together with the amounts of protein and volume of ascitic fluid removed at each paracentesis are recorded in graphs (Figs. 4 and 5). Exact data concerning analytical methods, the albumin content of the plasma and ascitic fluid, hematocrit and fibrinogen levels, and

Fig. 3. Infra red photograph showing collateral circulation of abdominal wall of dog 42-893.

nitrogen balance variations, were presented in the previous report (47), and will be referred to in general terms only.

The ascitic fluid was usually reddish with a specific gravity of 1.012–1.018, and a hematocrit of 1.0 to 0.2 per cent. The protein content fluctuated considerably under the experimental conditions, an observation readily apparent from the graphs. Electrophoretic studies showed a striking similarity of plasma and ascitic fluid protein composition, and Figure 2 illustrates a pattern comparison of these two fluids drawn on consecutive days and represented in Figure 4 period 3–4 when the plasma protein level was 7.5 grams per cent, and the ascitic fluid protein 6.3 grams per cent respectively. We are indebted to Dr. Eric Alling for performing and interpreting the electrophoretic studies.

EXPERIMENTAL OBSERVATIONS

The 2 dogs described in this report followed similar postoperative courses. Accumulation of ascitic fluid began a few days postoperatively, and weekly paracenteses were carried out. In 1 dog on which the operation of vein con-

SURGERY, GYNECOLOGY AND OBSTETRICS

restriction was performed to explore and anticipate difficulties in technique, about 1 liter of clear yellow fluid was found in the peritoneal cavity when the animal was sacrificed under ether anesthesia 5 days later.

Collateral circulation became evident in 4 to 6 weeks following operation. This is particularly evident in the female of the 2 dogs studied, since this animal had apparently had numerous offspring and had well developed mammary vessels. Figure 3 is an infra-red photograph illustrating this.

During the postoperative recovery period it was noted that the plasma protein levels gradually diminished and the ascitic fluid steadily accumulated. At the time, the kennel diet was largely a mixture of vegetable matter and grains (wheat, rice, and potatoes), and though not analyzed was definitely on the low protein side. About 5 weeks after the operation, the dog, 42-893, was placed on a high protein diet (period 1-4, graph I, Fig 4) consisting of 200 grams of cooked soy bean meal, 200 grams of cooked horsemeat, added vitamins and ferric citrate solution, with a daily nitrogen intake of 13.6 grams.

Graph I (Fig 4) illustrates the sequence of events and the response to high and low protein diets, with additions of sodium chloride and sodium-free seasoning, and intravenous plasma.

On the high protein diet, the plasma protein level rose rapidly to its former level of over 7.0

grams per cent, while the ascitic fluid increased in protein grams per cent, but diminished in amount to an astonishing degree. Instead of weekly paracenteses of 2500 to 3000 cubic centimeters of fluid, with amounts of protein up to 100 grams, weekly amounts of protein evacuated with only 25 grams of protein therein. The dog was returned to kennel diet (period 4-9, Fig 4) after 4 weeks of high protein diet, and immediately the fluid began to accumulate with concomitant fall in plasma protein levels. During this 5 week period, 6 paracenteses were performed yielding 13,060 cubic centimeters of fluid containing 475 grams of protein (a weekly average of 95 grams) while the animal's plasma proteins fell to slightly below 5.0 grams per cent. During the following 4 week period on high protein regimen (period 9-13, Fig 4) three paracenteses, yielding 1710 cubic centimeters of ascitic fluid containing 77.4 grams of protein, were performed and the dog's plasma protein level rose to and remained above 7.0 grams per cent.

In attempting to establish nitrogen balance studies, the dog was placed on a standard low protein diet with a known nitrogen content for 4 weeks (periods 13-17, Fig 4). This diet consisted of sucrose, lard, bone ash, vitamin supplements, with 30 grams of ground liver or horsemeat, and 600 milligrams of iron as ferric citrate. The nitrogen content was 1.5 grams

Fig 5 Dog 40-37 Experimental course of plasma protein, ascitic fluid protein, and paracentesis volumes and protein content

daily During the low protein interval, the plasma protein stabilized at slightly over 6 grams per cent Four paracenteses, which yielded 2905 cubic centimeters of ascitic fluid containing 128 grams of protein, were performed in this period, a decided contrast to the output of fluid and protein noted while the animal was on the kennel diet, also a low protein regimen Suspicion arose that factors other than protein intake were responsible for the fluid accumulation, or failure to accumulate One of these factors was presumed to be sodium chloride

Consequently after a period of rest on a high protein diet (period 17-20, Fig 4) and a period of exposure to low protein diet and stabilization of the plasma protein level at about 6 grams per cent (period 20-23, Fig 4), an additional 6 grams of sodium chloride in capsule form were given daily for a 10 day period (period 23-24, Fig 4) Immediately the ascitic fluid accumulation increased, fluid relatively poor in protein, while the plasma protein level dropped During this period three paracenteses, yielding 5390 cubic centimeters of ascitic fluid containing 110.5 grams of protein, were performed and the plasma protein levels fell to 4.0 grams per cent These

results compare favorably with findings noted in period 4-9 when the animal was on the kennel diet

In view of the remarkable change in both the circulating plasma protein levels, and the ascitic fluid production, brought about by the liberal addition of sodium chloride to the diet, it seemed pertinent to try a sodium free seasoning agent as another means of checking the relation of the sodium ion to ascitic fluid production For this purpose we used a sodium-free agent,¹ the trade name for which is neocurtesal¹

After a 3 week period of rest on the standard high protein diet (period 26-30, Fig 4), and a maintenance period on the standard low protein diet (period 30-32, Fig 4), with stabilization of the plasma protein level at slightly under 6 grams per cent, the dog was given 6 grams of sodium free seasoning agent in capsule form daily for a 10 day period (period 32-34, Fig 4) The plasma protein level did not perceptibly change during this interval, and remained just under 6 grams per cent There were no untoward or toxic effects of the drug,

¹The formula for the compound is potassium chloride 66.0 per cent ammonium chloride 12.0 per cent starch 17.0 per cent, potassium formate 3.0 per cent, calcium formate 1.0 per cent, and magnesium citrate 1.0 per cent The compound has a saline taste

SURGERY, GYNFCOLOGY AND OBSTETRICS

Fig 6 Dog 40-37 Microscopic section of liver showing thickened capsule, dilated subcapsular lymphatics, and dilated blood sinusoids

sodium-free seasoning agent indicating a completely neutral role in the fluid accumulating conditions of these experiments

Intravenous plasma as a method of maintaining the dog's protein level was tried as a related experiment. About 350 cubic centimeters of whole heparinized dog plasma with a protein content averaging about 22 grams were given daily for a 2 week period (period 24-26 Fig 4). Both plasma and ascitic fluid protein percent rose but the increased amount of ascitic fluid formation necessitated more frequent tappings. During the 2 week period 3 paracenteses were performed, which yielded 5810 cubic centimeters of ascitic fluid containing 232.6 grams of protein. Since during this period 306.4 grams of protein as plasma protein were administered, this represents a loss into the ascitic fluid equivalent to 75 per cent of the injected protein. A second administration of plasma to the same dog for a similar period, which is not shown on the graph, resulted in a loss equivalent to 65 per cent of the injected protein, 197 grams of protein being removed as ascites against 301 grams administered as plasma protein.

Throughout the experiments the urinary nitrogen kept pace with protein intake, and the nitrogen balance studies revealed a positive balance when the animal was on a high protein diet and building plasma protein, and a negative nitrogen balance when the dog was on a low protein diet and the plasma protein was falling.

A second dog, 40-37, a male, was surgically prepared in the same manner, though the band was not so tightly constricted. The responses to diet are illustrated in graph II, Figure 5 and are much the same as in the first dog with concomitant rises and falls in the plasma and ascitic fluid protein percentage levels. During the periods of high protein regimen, the plasma and ascitic fluid protein percentage rose while both the amount and total protein content of the ascitic fluid fell. The reverse was observed during periods of reduced protein intake.

Intravenous plasma was also given to an animal with results similar to those of the first dog. During the 2 week period (period 14-16 Fig 5) four paracenteses

the animal remained alert, active, and in good health with formation of only a small amount (670 c c) of ascitic fluid containing 20 grams of protein.

Immediately following this 10 day period, the dog was continued for a 7 day period (period 34-35 Fig 4) on the low protein diet, with 6 grams of sodium chloride replacing the 6 grams of neocurtal. Immediately the plasma protein level began to fall and fell steadily reaching 4.2 grams per cent at the end of the period. Increased amounts of ascitic fluid necessitated three paracenteses totalling 4250 cubic centimeters and containing 60 grams of protein during this period. It is readily apparent that the sodium ion is an important factor in the ascitic fluid formation in this type of experimental animal.

After a 3 week period of recovery on a high protein diet (period 34-37 Fig 4) the animal was carried for an additional week on the horse-meat but was given 6 grams of neocurtal daily in addition (period 38 Fig 4). The protein level was maintained during this interval at slightly over 7 grams per cent, and only a small amount (450 c c) of ascitic fluid containing 18.8 grams of protein was formed. This provides further information about the

necessary, with 4830 cubic centimeters of ascitic fluid containing 245 grams of protein resulting. Plasma protein level rose from 4.7 grams per cent to 6.7 grams per cent during the period of plasma infusion. The dog received 321 grams of protein as plasma protein during this 2 week span, so that the 245 grams of protein removed in the ascitic fluid represent a loss equivalent to 76 per cent of the administered protein. During the period of plasma injection, the dogs were given 50 grams of glucose together with a multiple vitamin mixture in 300 cubic centimeters of water by stomach tube as a dietary supplement. When the large accumulation of ascites was noted, it was not possible to exclude the additional amount of fluid given in the plasma plus the water by stomach tube as a cause for increased ascitic fluid formation. It was also noted that while the dogs were on the high sodium chloride regimen, the fluid intake quite naturally increased. To rule out increased fluid ingestion per se as a cause or even a contributing cause of ascitic fluid formation, the dog was given 800 cubic centimeters of water plus the previous dose of multiple vitamins each day by stomach tube in addition to its normal desires and diet (period 19-20, Fig. 5). There was no appreciable change in the ascitic fluid accumulation and no change in the plasma protein level during a 1 week period of forced fluid ingestion.

The effects of liberal sodium chloride in conjunction with a high protein diet were also studied (period 20-22, Fig. 5). The animal was given 300 grams of horsemeat with the usual vitamin and iron supplements as a daily diet plus 1 gram of sodium chloride in capsule form six times a day. This experiment was continued for 2 weeks, during which period there was no appreciable rise in the plasma protein per cent. At the beginning of the experiment this plasma protein level stood 5.2 grams per cent, and after 2 weeks with minor fluctuations it had fallen to 4.7 grams per cent in spite of the ample protein intake. There was a marked increase in the formation of ascitic fluid with large amounts of protein therein, and 5 paracenteses containing a total of 233 grams of protein were performed during the 2 week period, none of which yielded less

than 1200 cubic centimeters of fluid. Apparently the protein from the diet, which the animal was able to utilize, was washed out and transformed into ascitic protein as a result of the sodium chloride activity.

Thus far we have described and demonstrated the effects of high and low protein diets, additional sodium chloride, fluid, and sodium-free seasoning agent, and plasma intravenously on the protein metabolism of this type of experimental animal. The anatomical findings are also of interest.

The second dog, 40-37, was operated on initially with placement of the constricting band about the vena cava, on December 18, 1946. A second operation was performed on January 7, 1948 with complete ligation and section of the vena cava. The animal responded poorly from this second procedure and became increasingly inactive, succumbing 13 days after operation. At autopsy approximately 1500 cubic centimeters of ascitic fluid were found. Collateral vessels in the omentum were well developed, with adhesions and connections to the vessels of the peritoneal surfaces. Vessels in the mediastinum and throughout the pleural surfaces of the diaphragm were likewise enlarged. Azygos veins were dilated. Numerous fibrous and fibrinous adhesions were present about the liver. The cause of death was determined to be acute pyloric ulceration with massive intestinal hemorrhage.

The liver weighed 500 grams. There were numerous grayish areas of fibrosis in the capsule and both interlobar adhesions and adhesions to the diaphragm and surrounding structures were present. The parenchyma showed numerous nodular deformities. On section, the organ showed a subcapsular zone measuring about 0.5 centimeter which was greatly congested. Numerous nodular areas of paler regenerating tissue intermingled with darker congested tissue were noted. The central areas were dilated and congested, and appeared dark red against a yellowish gray background.

Histologically, the lobular structure was fairly well preserved. The subcapsular sinusoids and lymphatics were greatly dilated and the sections appeared almost hemangiomatous.

in places (Fig 6) The subcapsular liver cells were large and pale and contained considerable glycogen The remainder of the parenchyma showed numerous focal necroses and the portal vessels were greatly dilated in every case

The first dog, 42-893, is still alive and well, 27 months after placement of the constricting band Biopsy of the liver performed under nembutal anesthesia through a small abdominal incision on June 15, 1948, 22 months after placing the band, showed a similar microscopic picture

Liver function does not seem to be seriously affected Thymol turbidity tests were negative Bromsulfalein clearances showed 6 per cent retention in the first dog, 42-893, 9 months following placement of the band, and a mere trace of retained dye 2 years after operation The second dog, 40-37, showed a 7 per cent retention 6 months after operation Fibrinogen levels vary with the levels of other proteins Blood chloride determinations fell within normal limits, and when the animal was on a diet with extra sodium chloride added, the ascitic fluid chlorides rose as the ascitic fluid proteins declined

DISCUSSION

The marked influence of the sodium ion on the accumulation of ascitic fluid and hence on the protein metabolism of this type of experimental animal is indicated This influence is supported actively, as well as passively, by the data presented in this report The administration of 6 grams of sodium chloride daily with both high and low protein diets caused a depression of the plasma protein per cent levels and the accumulation of ascitic fluid containing much of the lost protein The mere forcing of fluids in the absence of sodium chloride, the administration of sodium-free salt in amount equal to the sodium chloride dosage, the administration of diets low in sodium chloride, do not produce this effect The administration of whole dog plasma, containing the normal amount of circulating sodium chloride does produce it, for while there is a rise in circulating plasma protein, there is also a great increase in ascitic fluid protein, equivalent to approximately 75 per cent of the injected plasma protein This effect is similar

to that seen in humans with ascites who receive whole plasma The success of salt-poor or salt-free albumin in the treatment of human ascites may be attributed more to the paucity of sodium chloride in the solution than to the oncotic pressure of the protein

The effect of the high protein diet per se on the accumulation of ascitic fluid in these animals is also noteworthy The amount of ascitic fluid produced is greatly decreased, even though the protein grams per cent therein may be raised Thus by use of a high protein diet, with attention to the sodium intake, the second dog, 40-37, remained free of ascites for 5 weeks (period 23-28, Fig 5) and later for a 3 month period not shown on the graph

The large protein output of the dogs by way of the ascitic fluid compares very favorably with the production of protein by standard hypoproteinemic dogs undergoing plasmapheresis (38) These standard hypoproteinemic animals may reach an output of 70 grams of new plasma protein per week in a 10 kilogram dog The experimental ascitic dog by way of internal plasmapheresis may produce as high as 95 grams of new protein per week (period 4-9, Fig 4) Even allowing for a carry over from the preceding high protein regimen, and the drop in the concentration of the circulating plasma proteins, we have at least a normal high plasma protein output by way of the removed ascitic fluid This suggests that the vascular stasis has not seriously interfered with the ability of the hepatic epithelium to manufacture plasma protein

Recent literature reporting the findings in cirrhotics after albumin therapy and reviewed above (1), raises questions which disturb the validity of Starling's hypothesis The actual source of ascitic fluid is not known, but from the work of Grindlay and our own observations (59), it is suggested that the liver is an important source Experiments in banding and ligating the portal vein and vena cava below the liver fail to produce ascites (9, 58) It seems logical to conclude that the ascitic fluid results from the stasis of blood in the liver sinusoids that dilate with transudation of protein-containing fluid into the subcapsular lymphatics and ultimate accumulation in the peritoneal cavity (Fig 6)

Additional work is needed, particularly observations on human subjects, but there seems to be every indication that the salt free diet and high protein diet have a definite place in the treatment of the ascitic patient, even as in the edematous patient of cardiac and renal disease

SUMMARY AND CONCLUSIONS

1 Ascites may be produced experimentally in dogs by constricting the inferior vena cava above the diaphragm to about one-half its original diameter, with an aluminum band

2 The transthoracic operative procedure is described in detail

3 Ascitic fluid begins to accumulate within a few days postoperatively, and the rate of formation and protein content are influenced by diet and sodium chloride intake

4 Sodium chloride, added daily to both high and low protein diets, causes a depression in the circulating plasma protein per cent and increased accumulation of ascitic fluid. This ascitic fluid contains the equivalent of much of the lost protein from the circulating plasma

5 Administration of sodium free salts in amounts equal to the sodium chloride dosage and administration of diets low in sodium chloride produces no change in circulating plasma protein per cent and no significant variation in ascitic fluid production

6 Forcing fluids with a low sodium chloride intake produces no change in circulating plasma protein per cent and no significant variation in ascitic fluid production

7 Administration of whole dog plasma intravenously causes a rise in circulating plasma protein per cent, but at the same time promotes a marked increase in ascitic fluid formation and its protein concentration. This increase in ascitic fluid protein content is equivalent to approximately 75 per cent of the injected protein

8 The weekly protein output of the experimental ascitic dog (80-95 grams) compares favorably with that of a standard hypoproteinemic dog undergoing plasmapheresis (70 grams)

9 The question of the source of ascitic fluid is raised

THE POSTPHLEBITIC LEG

Results With Femoral Vein Interruption

S THOMAS GLASSER, M D , F A C S , New York, New York

IN view of the multiplicity of sequelae and the varied pathologic states that usually follow iliofemoral thrombophlebitis, it is not surprising that more than one type of treatment becomes necessary. However, in our experience, the one essential in therapy is femoral vein interruption. The signs and symptoms as well as the physiologic aspects of the postphlebotic leg have been well described in the literature (1-6, 8-10, 12, 15-31). However, brief mention of the essential phases which led up to the sequelae will bear repetition for a better understanding of the treatment with which this presentation is concerned. The history is frequently so typical, that the diagnosis is obvious. The pathologic changes and the signs and symptoms are in the main the consequences of sustained chronic venous insufficiency. This is manifested by the following sequelae which vary in severity: edema, eczema, pruritus, pigmentation, pain, secondary varicosities, recurrent lymphangitis, indurated cellulitis, and ulcers.

Our discussion pertains chiefly to femoral vein ligation as a therapeutic measure in the treatment of the late results of thrombophlebitis—the postphlebotic leg. Femoral vein interruption as a method of treating these late sequelae, a method which would directly stop the venous back pressure, was suggested by Homans (17) in 1941. He stated that “exploration of the femoral and iliac veins may be called for to correct peripheral vasospasm in the limb served by the diseased vein, to oppose recurrence of attacks of femoriliac thrombophlebitis and conceivably, once the femoral vein has suffered destruction of its valves by earlier attacks, to prevent backflow down the vein, the same purpose for which a varicose vein is divided at the groin. Obviously,

the femoral system, once thrombosed, must suffer the loss of all its valves (there is rarely one in the external iliac vein and none above), so that when the body is erect, the venous return must take collateral, valved pathways. Blood must pour down a valveless vein, and it is therefore reasonable to assume that an old, sclerosed, and canalized femoral vein or external iliac vein is better divided.” In 1944, Buxton (8) and his co-workers published the first clinical report on the utilization of femoral vein ligation for the treatment of the postphlebotic state in 21 cases. The majority of these cases consisted of chronic ulcerations, but in some patients the major complaints referred to swelling, pain, and easy fatigue. In most of these cases the superficial varices had been ligated before femoral vein interruption was attempted. The authors were of the opinion that arteriosclerosis was a definite contraindication to femoral vein ligation and established 55 years as the age limit for this operation. The results were good in the ulcer cases but uncertain in the others. This series may be analyzed as follows: In 16 of the 21 patients, improvement was definite, 6 of the 21 developed superficial varicose veins following femoral vein ligation and these were ligated as they appeared, in 7 cases persistent or increased swelling followed by bed rest, in the 14 ulcer cases, all were improved—complete healing in 4, progressive healing in 4, no change in 4, and in the remaining 3 cases operation was too recent to permit proper evaluation. The following year (1945), Buxton and Coller (7) published a supplemental report and added 3 cases to their original list. Their conclusions were essentially the same as previously reported, that the procedure, femoral vein ligation, was of value only in the presence of stasis ulcers. Linton, Hardy, and Irad (23) reported on 34 patients in 1947 in

cluding a follow-up of 2 to 14 months. In addition to femoral vein (superficial femoral) ligation, interruption and stripping of the long and short saphenous veins were performed. The stripping procedure was extended down to the medial malleolus. At the time of operation, venous pressures of both the superficial and deep veins were ascertained in order to determine whether or not simultaneous ligations were advisable or whether a two stage operation was to be selected. A marked increase in pressure in both veins precluded concomitant ligations. The results were encouraging enough for further clinical use of the method. Again, in 1948, these authors (24) published a supplemental report on 49 patients with the same satisfactory results. They formulated a routine plan for the treatment of ulcer. The ulcer is given first consideration because femoral ligation performed in the presence of an infected ulcer (as most cases actually exist) is fraught with danger. Ordinarily, the ulcer is healed before the femoral vein is interrupted except in the case of very large ulcers in which hospitalization is necessary for wet dressings and elevation followed by skin grafting. The femoral ligation is then performed 10 days later. Penicillin is given preoperatively and postoperatively.

It is appreciated by most workers that bed rest with elevation frequently enables healing of the ulcer, the beneficial effects being directly related to the control of the venous back pressure. In addition the infection is permitted to come under control. It is obvious that edema should be reduced or eliminated before definitive treatment is attempted. Again, it is also evident that edema must be initially prevented immediately postoperatively to give every chance for "takes" with skin grafts. Any of the many suitable elastic leg supports may be utilized. Sclerosing agents for the superficial varices are generally supposed to be contraindicated because of the possible effect on the deep veins. However, it would seem plausible that the development of occasional new varicosities can readily be controlled by sclerosing therapy. An exception to this is the presence of obvious tender superficial thrombotic phlebitis. In addition to clearing up the local infection, epidermophy-

tosis should also be treated since superimposed secondary infection as well as allergic phenomena are common accompaniments. Potassium permanganate in 1:5000 dilution is of value for this complication. When bed rest is not possible and if the ulceration or the cellulitis or both are not marked, ambulatory treatment may also effect a temporary healing. This treatment includes support by elastic bandage, elastic stocking, elastic adhesive, gum rubber bandage, or Unna paste boot. A properly shaped rubber sponge directly over the ulcer and under the elastic support is of real value. For the concomitant eczema or dermatitis, local applications consisting of bland ointments or lotions are salutary. Much time may be saved in cases of large indurated ulcers by excision and split skin grafts. When the induration is more extensive and continuous for varied distances into the adjacent subcutaneous tissues, a Kondoleon or modification of this operation may be done in conjunction with a skin graft.

DeTakats and Fowler (11) have experimented with the application of x-rays for their absorptive effect on periphlebitic infiltration and exudation. This method has not been evaluated to date. Allen, Barker, and Hines comment unfavorably on the use of both x-ray and ultraviolet for the postphlebitic leg.

Another form of treatment which Wright claims to be of value is mecholyt iontophoresis applied three times weekly. The beneficial results with this method are said to depend upon the vasodilatory effects.

In the treatment of the secondary varicose veins, a safe general rule is to perform multiple superficial ligations whenever incompetency of the saphenous system can be demonstrated. As previously described, these varicosities are the outcome of increased venous back pressure which takes place when canalization of the deep veins occurs. However, secondary involvement of the superficial veins is not as generalized as might be expected. It would appear to us that the involvement is equally likely to be "spotty" or segmental. To all intents and purposes, when primary varicose veins are present the edema which develops is the same as in the case of equally incompetent secondary varicosities. The presence of

GLASSER POSTPHLEBITIC LEG

543

isolated dilated superficial veins needs no surgical intervention (ligation) unless a "blow-out" demonstrating incompetency of the local communicating vein is present. Although we have no figures to show the incidence of superficial vein inadequacy, we believe that the number of cases in this category is not as great as mentioned by Linton and others. Furthermore, the technical difficulties encountered in the stripping of such veins and the morbidity which might be expected as a result of such a procedure presents a real problem. Not infrequently, "intradermal" varicosities, especially below the knee (uncommon in the thigh), are encountered. These veins are impossible to strip. They can be removed only by excision in most cases, and if they are located in the vicinity of an ulcer or induration, the dangers of infection and nonhealing are real. Multiple properly placed ligations should be satisfactory.

Another procedure which is part of our armamentarium is lumbar ganglion novocain block. This is of definite value whenever signs or symptoms of sympathetic nerve irritation are in evidence, e.g. clammy sweaty cool skin, diminished pedal pulse volume, and pain. Not infrequently, lumbar ganglionectomy is indicated when sympathetic block shows temporary improvement and a sustained effect is desirable and necessary. From the prophylactic viewpoint this procedure may be of additional value in the prevention of recurrent attacks of thrombophlebitis. In the further care of the postphlebitic syndrome, the multiplicity of methods in treatment should also include the eradication of foci of infection, e.g. tonsils, teeth, etc. The direct relationship of these to recurrent inflammatory bouts in the extremities is more than likely. On occasion we have found sensory nerve block of the internal malleolus. The less frequent ulcer with pain over the lateral malleolus can be treated by injection of the sural nerve, whereas blocking the long saphenous nerve will anesthetize the medial aspect of the ankle. This is a simple office procedure.

A high percentage of postphlebitic legs are associated with flat feet. The weakened arches are attributed to the venous pathology

Pressure on the plantar vessels follows and in addition initiates reflex vasospasm. A natural sequence of flat feet which contributes to venous stasis is atrophy of the leg muscles. Since the venous return is normally aided by the efficient action of muscle contraction, stasis is augmented when muscle atrophy is present.

With all the foregoing, one must not forget that a proper general physical examination is essential to rule out contributory disease, such as blood dyscrasias (polycythemia), myxedema, cardiac and renal pathology, arteriosclerosis obliterans, intrathoracic or intra-abdominal malignancy. The conditions just enumerated may be of real etiologic significance in the causation or tendency to edema or venous thrombosis or both. Since the diagnosis of the postphlebitic syndrome is not always an easy one to make, differential diagnosis must necessarily take into consideration the possibilities previously mentioned. For instance, we are all familiar with the high incidence of deep vein thrombosis associated with malignancy. The neoplasm, whether intra-abdominal or intrathoracic, may not be obvious and its presence discovered only during thorough routine examination. Not infrequently this type of malignancy is the actual cause of recurring phlebitis.

Concomitant lymphatic obstruction may be estimated from the information elicited in the history, the presence of a persistent brawny edema with thickened skin, and of even greater significance, the observation that the edema decreases very slowly with elevation and bed rest as compared with the venous type of edema.

The familiar phrase, "let us individualize our cases," applies particularly to the subject of treatment of the postphlebitic leg. The discrepancies in published results lie in attempts to use one form of treatment exclusively for the postphlebitic syndrome. The varied pathology manifested by sequelae in different stages obviously requires varied therapeutic procedures or a combination of treatments. In order properly to evaluate any one form of treatment, similar stages in the disease must be compared. To this end, a working classification such as that given by Ho-

mans (18) is valuable. This author reported on 156 cases and divided them among 5 groups. Individual treatments were referred to each group. In group 1 are those cases characterized by edema of the ankle and lower leg which swells somewhat during the day but disappears or diminishes overnight. The extremity appears normal in all other respects. In group 2 which is the largest one, in addition to edema there is pigmentation, induration, ulceration, or combinations of these. In group 3 the prominent feature is pain which appears early in the postphlebotic history. Vasomotor changes are often present. In group 4, with the least number of cases, marked venous congestion is prominent and distended superficial veins are seen. In group 5, of moderate frequency, the characteristic features are recurrent thrombosis in both deep and superficial veins. These episodes are occasionally associated with nonfatal emboli.

The preceding classification is valuable if one attempts to outline the various methods of treatment essential to each phase of the disease. Although we have not adhered to this suggested outline, in essence, we have unintentionally allowed our treatment to follow such a prescribed pattern. Our extensive experience with femoral vein ligations in the treatment of arteriosclerosis obliterans (13, 14) and also with vein interruption of the inferior vena cava and iliacs as well as the femoral for phlebothrombosis has given us confidence in the technical management of this procedure. We feel that interruption of the femoral vein immediately distal to the profunda branch is a harmless procedure if performed by those who have had experience in vascular surgery. Arteriosclerosis and the age limit of 55 years have been mentioned as contraindications to femoral vein ligation (7, 8). From our experience (13, 14), we cannot agree with this viewpoint. The poor or ineffectual results of femoral interruption in those cases of the postphlebotic leg in which ulcers were absent, as mentioned by Buxton (8) and his co-workers, is also contrary to our experience. We are unable and therefore make no attempt to explain some of the failures as noted in our statistics, first because of the frequent inaccuracy of a clear cut pathological picture, and

secondly because an evaluation would be chiefly on the theoretical side. However, we do have an overall clinical picture and impression as will be noted in a tabulation of our results later on.

In view of the difficulty of follow-up examinations in many of our cases—particularly those from one of our hospitals where only the indigent are treated—it would be impossible and certainly inaccurate to attempt to estimate the individual values of the various methods used in the treatment of chronic thrombophlebitis. It is obvious that data regarding a patient with a healed ulcer are of no value if further follow-up is not carried out after discharge from hospital. Statistical reports which fail to take this viewpoint are usually enthusiastic in their claims, thus the high percentage of "cures" with any one method. We have therefore omitted from our evaluation much unobtainable but desired and necessary information. However, the figures which we do have at hand are reasonably accurate, instructive, and informative.

An analysis of 91 cases of thrombophlebitis in 71 patients is sufficiently comprehensive in only 40 cases in which follow-up was possible. Therefore the total number of cases will be included only wherever data are of value.

In the 71 patients on whom the superficial femoral vein was interrupted immediately distal (below) to the profunda branch, 20 were bilateral, making a total of 91 limbs operated upon. The youngest patient was 28 years old (1 case), 5 patients ranged in age from 30 to 35 years, 6 from 36 to 40 years, 20 from 40 to 50 years, 24 from 50 to 59 years, 9 from 60 to 70 years, 6 from 70 to 80 years. The sex incidence was 48 females, and 23 males, a ratio of more than 2 to 1. The origin of the primary thrombophlebitis was indefinite or vague in so many cases that a comparative percentage of incidence relative to either postpartum, postoperative, or postmedical source could not be ascertained. However, many of the patients could approximate the beginning of their "leg trouble" or "swelling." In other words, a "swollen" leg was recalled but without any definite association to a specific illness in the past. A close approximation of the duration of the postphlebotic state revealed the short-

est interval at 3 years in 1 case, the longest at 30 years in 9 cases. The greatest incidence was at 5, 10, and 20 years in 12, 16, and 15 cases, respectively. In 18 cases, the time element was doubtful. This negative point in the history would make us conclude that the original thrombophlebitis was probably not of the phlegmasia alba dolens type but one in which swelling was moderate or slight or in which the symptomatology at the time was not pronounced. Not too long ago, there were many patients who for economic reasons could not afford to be idle and thus neglected a leg condition, particularly if the signs and symptoms were of minor degree. The high incidence of ulcer as a complication—58 cases—was noted in our series. The presence of other associated complications, such as indurated cellulitis and eczema with or without ulcer, was also frequent. Of special interest is a compilation of surgical methods other than or in addition to femoral vein ligation as recorded in our series. The ulcer was excised and split skin grafts used in 20 cases. This procedure was done prior to femoral interruption in 8 instances and after in 12. The failure of "takes" when grafting preceded other measures was 6 out of 8 operations. The "takes" following femoral ligation were 10 out of 12. These are significant findings, and tend to prove that successful skin grafting is unlikely unless venous stasis is relieved.

Lumbar ganglionectomy (second and third lumbar) was employed for two reasons: (1) to overcome associated vasospastic phenomena, and (2) to improve the arterial blood flow and thus enhance healing of the ulcer. The first objective was attained with uniform success. The second (healing of the ulcer) appeared clinically to be of definite value. There were 8 cases in which lumbar ganglionectomy was indicated following femoral vein ligation. In these, sympathectomy greatly benefited the healing of ulcers which had been refractory to interruption of the femoral vein as well as to other measures. In the 24 cases in which sympathectomy was carried out preceding femoral ligation, the results were good in 12 and without apparent improvement in 12. However, healing followed femoral vein ligation in the latter group.

Lumbar sympathetic blocks with novocain were utilized in 40 patients before the femoral vein was ligated. This procedure was of definite value for the reduction of swelling in 21 of the 40 cases. It succeeded where the edema was of the "soft" type and where evidence of lymphatic obstruction was not apparent. Its value for the relief of pain was definite, being successful in all but 12 cases.

The necessity for saphenous vein ligation subsequent to femoral interruption was deemed advisable in only 12 cases of our series. Ligation of the superficial veins was always multiple. This measure resulted in healing in 9 of the 12 cases. In only 1 instance was concomitant vein ligation employed, i.e. saphenous and femoral veins ligated in one stage. This was done because of an accidental injury to the saphenous vein which necessitated ligation of this vessel in addition to the scheduled femoral interruption.

Sensory nerve block for allaying the pain of indurated cellulitis or ulceration was employed 14 times with uniformly good results. The long saphenous nerve was injected in 10 limbs, the sural nerve in 3 legs, and the superficial peroneal nerve in 1 case. This procedure is of real value and should be employed more often than it has been in the past.

There was no mortality in our series of 91 ligations. The morbidity was negligible. Two infected wounds cleared up within 1 week. The only annoying symptom was pain along the distal course of the femoral vessels, particularly over the inner aspect of the knee. This occurred in 9 cases and was usually accompanied by a moderately elevated temperature lasting 3 to 7 days. The pain lasted 4 days in 6 cases and 10 days in 3 cases. This complication is due to a spontaneous "aseptic" thrombosis which takes place in the femoral and popliteal veins following the operation. The mechanism is probably the same as occurs so frequently following simple ligations for primary varicose veins. Moderate postoperative edema was present in 12 cases. The swelling subsided in 1 week. In 2 cases, edema was marked. Of these, one cleared up in 12 days while the other was improved on discharge from the hospital, the edema completely subsiding after 6 months. There were

28 cases in which paresthesia over the inner aspect of the knee was present. This was due to the operative manipulation of the internal femoral cutaneous nerve or perhaps as a result of inflammation as part of the healing process. In nearly all instances, the paresthesia was either in the form of a partial localized skin anesthesia or an uneasy "awareness" in the skin overlying the inner aspect of the knee. The duration of the paresthesia was approximately 7 to 10 days.

Forty patients were examined in follow-up. Only 3 patients could be followed for 5 years and 3 for 4 years. The results were good in these few, only 1 of the 6 had a recurrence of the ulcer. In this instance, the possibility of trauma as the etiologic factor in the recurrence was probable but not certain—this patient's mental status was below par. The relief of pain and cellulitis were also noteworthy findings. Edema was 1 plus in the case of the ulcer recurrence. Of the 8 cases in the 2 year follow-up the incidence of ulcer recurrence was 50 per cent. However, trauma was a definite factor in 3 of the 4 recurrences and also accounted, at least in part, for the 2 instances of indurated cellulitis. The greatest number of cases which were rechecked were in the 1 and 2 year groups—22 cases. Here again, trauma accounted for 3 of the 6 recurrences of ulcer. In the remaining 4 patients who were examined in 6 months, no ulcers had recurred. The salutary effects of femoral vein ligation on eczema were obvious in our series. The presence of epidermophytosis was the most prominent cause for refractory behavior and response of the eczema.

SUMMARY

1 A description of the postphlebotic syndrome, the sequelae of iliofemoral thrombophlebitis, is reviewed.

2 The physiology and pathology are described in detail to explain the varied pictures of these sequelae.

3 The treatment is not always simple. Multiple procedures may be necessary for satisfactory results. The various surgical measures are enumerated.

4 Satisfactory results are noted in our follow-up of 40 cases.

5 The operation of femoral vein ligation has not been attended by any mortality in our series. The morbidity is only slight.

6 The importance of femoral vein ligation immediately distal to the profunda branch as it is applied to our 91 ligations, is emphasized.

7 Femoral vein ligation is the one therapeutic measure which is essential in the treatment of the postphlebotic state.

THE MODERN SURGERIES OF THE PROSTATE

CLYDE L. DEMING, M D, F A C S, New Haven, Connecticut

THE pendulum of opinion has swung from one method of prostatic surgery to another several times within the memory of present-day surgeons, and popular medicine has wavered in its advocacy of the various methods of prostatic surgery, first urging one method and then another. For 50 years perineal prostatic surgery has been strongly advocated in this country, and the suprapubic approach has an even longer herit-age in the field of surgery. Transurethral re-moval of sufficient prostatic tissue to allow micturition has had a 30 year active tenure, and many modern surgeons still have faith in its application for all forms of prostatic and bladder neck obstructions. So much has been published in lay periodicals concerning trans-urethral "surgery" that patients knowing nothing about prostatic obstruction, its cause, its development, its pathology, its surgical morbidity or its mortality, now come to the surgeon requesting him to operate by the transurethral route. Recently, the retropubic approach, an old procedure, has been revived, with many surgeons as advocates. Proponents of the various methods of prostatic surgery have not only been successful in clinical prac-tice but have also succeeded as teachers in medical schools in propounding their chosen method of prostatic surgery as the superior method for the treatment of all prostatic ob-structions. Is there any gyroscope to indicate what the modern surgery or surgeries of the prostate are today? This question can be par-tially answered by the interjection of another question which sounds distinctly modern. Why are so many young prospective urologi-cal surgeons applying for positions where they can obtain training in all methods of prostatic surgery? All of these men have, or plan to have, a broad training in the basic sciences of physiology, bacteriology, pathology and tumor growth, and lastly surgery. Needless to say, most of the general surgeons of today foresee the necessity for such a broad basis of surgical training. The fact that these young men seek a broad training in prostatic surgery implies that there must be a certain amount of logic which can be applied to prostatic surgery and furthermore it carries a real significance and imposes an actual teaching responsibility on our medical schools.

Surgery of the prostate depends on many factors, such as the character of the obstruc-tion, infection and allied complications. Is the tumor large or small, is it composed of one, two, or three lobes, and do they grow intra-vesically or extravasically, is there infection of the bladder, prostate, epididymis and kidney, is the infection responsive or resistant to the antibiotics, or is the patient allergic to the antibiotics? Too little has been said and writ-ten as to the character of the growth of the prostatic tumor causing the obstruction. The size of the tumor gives no indication as to the amount of obstruction or the volume of re-tention of urine, the author has had physi-cians as patients who had minimal urinary symptoms and who were unaware that they carried 1600 cubic centimeters of residual urine. Some prostatic enlargements are due to prostatic calculi, benign cysts, and abscesses, while others are of a malignant nature, and the differential diagnosis must be made. All too frequent are the bladder complications diverticula which do not empty are associated with prostatic obstruction in 8 per cent of patients, calculi, in 20 per cent, carcinoma, in 2 per cent, and papillomas, in 9 per cent. Re-nal calculi are present in 5 per cent, ureteral calculi, in 5 per cent, and renal cancers, in about 2 per cent. Urethral strictures occur not infrequently and give preoperative and postoperative concern. Renal function is often seriously impaired due to back pres-sure and infection in patients with retention of urine. In the very old patients cardiac and

both ureters into the sigmoid for cancer of the bladder and at the same time removing the bladder, prostate, and seminal vesicles, has sound principles when we have at our command urinary and bowel antiseptics, blood electrolyte control, and protein balance and vascular support

SUMMARY AND CONCLUSION

One hundred patients with prostatism were admitted to this hospital between 1878 and 1908. The majority of them were treated with catheter drainage, 20 were operated upon, 10 suprapubically and 7 perineally, and 3 had castrations, although at that time no differentiation was made between benign and malignant lesions of the prostate. Although an enlargement of the prostate was recorded at the time the bladder was opened suprapubically no attempt was made to remove it except in 1 case, in which the patient died. The surgeon's eyes were focused upon the bladder calculi. The mortality was appalling, being 45 per cent for all patients admitted. During the years 1910 to 1920 the mortality rate in this institution for prostatic surgical patients was 39 per

cent. For the past 6 months, 100 patients with prostatic disease have been admitted with a mortality of 2 per cent, and those 2 deaths occurred in patients admitted in the last stages of cancer of the prostate. All types of prostatic operations have been done by various members of the urological staff. For the benign overgrowths, 60 per cent were done perineally, 20 per cent suprapubically, 15 per cent, transurethrally, and 5 per cent, retro-pubically, for the carcinomas, perineal biopsies, total and radical prostatectomies, as well as conservative perineal excision for relief of obstruction when residual urine was present.

There is hardly an organ of the human body which presents as many opportunities for surgery as the prostate. The different ways in which the benign tumor grows, the tendency for frequent cancer development, and the associated complications involving the bladder and kidney and cardiovascular system all demand surgical consideration. In order to obtain the best results in every case, all the operative procedures have their place if correctly applied, and they should be so taught in our hospitals and medical schools.

THE ENDOMETRIUM IN OLD AGE

HAROLD SPEERT, M D, New York, New York

THIS is a study of the normal postmenopausal endometrium. Although knowledge of the cyclic morphologic changes exhibited by this membrane during the menstrual era has been on record for over 50 years, an adequate description of its postmenopausal picture has probably been retarded by the assumption that it participates in the obvious general involutionary changes in the genitalia. A partial search of the literature, including a random selection of the textbooks on gynecology and gynecological pathology of the last half century, for a systematic study of the normal postmenopausal endometrium has proved fruitless. Only a few authors accord it even brief attention, all without references to any original work on the subject. These brief descriptions of the senile endometrium emphasize the atrophy of the glandular elements and a few take note of the occasional cystically dilated gland.

Interest in the postmenopausal endometrium was aroused by three studies (Breipohl, 1935, Taylor and Millen, 1938, Novak and Richardson, 1941), all of which reported the unorthodox finding of hyperplasia in a fair proportion of cases. Breipohl found hyperplasia in 15 of 130 postmenopausal endometria. His series, however, included patients with as little as 6 months' amenorrhea, and 2 of his patients had granulosa cell tumors of the ovary. Taylor and Millen described a hyperplastic endometrium in 3 of 34 patients with otherwise normal pelvic organs, 4 to 13 years after the menopause. Surprisingly high was the incidence of hyperplasia, either frank or "retrogressive," reported by Novak and Richardson in almost half of a series of 137 endometria from women 2 to 40 years beyond the menopause. These observations have forced a reconsideration of the traditional concept that the postmenopausal endometrium is necessarily an atrophic one.

From the Department of Obstetrics and Gynecology College of Physicians and Surgeons Columbia University

Despite their great value in awakening interest in the senile endometrium and in demonstrating its potentialities, previous reports suffer from two serious shortcomings which render their applicability to normal histology dubious. First and most important is the fact that almost all of the specimens were obtained from women with gynecologic disorders, bleeding being their foremost symptom. This makes the material a highly selected one in which abnormalities of the endometrium would be expected with a much higher frequency than among an unselected group of postmenopausal women of comparable age. Second, many of the endometria were classified from the examination of curettings. In a significant proportion of the cases no endometrium was obtained. Exclusion of such cases, as was done by Novak and Richardson, undoubtedly resulted in an artificially low incidence of atrophy. On the other hand, the classification of every endometrium as atrophic solely on the basis of a nonproductive curettage, as was done by Breipohl, would hardly seem justified either. Furthermore, microscopic interpretation of curettings from a postmenopausal uterus is often difficult, because of the fragmentation of the tissue and the ease with which the commonly encountered endometrial polyps may be confused with the diffuse type of hyperplasia (Kottmeier, 1947).

PRESENT STUDY

The material on which this study is based consists of 60 normal uteri which were removed incidental to vaginal plastic operations because of varying degrees of descensus. Only those cases were included in which at least 2 years had elapsed since the last menstrual period. Except for this criterion there was no special basis for selection. The patients ranged in age from 50 to 85 years. 14 were between 50 and 55 years old, 19 between 56 and 60, 15 between 61 and 65, 10 between 66 and 70, 1

between 76 and 80, and 1 between 81 and 85, a total of 60 patients. About two-thirds of the patients had ceased menstruating within the preceding 15 years, the rest extending as much as 35 years beyond the menopause. In 10 patients the postmenopausal interval was 2 to 5 years, 6 to 10 years in 14 patients, 11 to 15 years in 18, 16 to 20 years in 8, 21 to 25 years in 8, 26 to 30 years in 1, 31 to 35 years in 1. In 16 cases curettage had been performed immediately preceding hysterectomy but in each instance sufficient undisturbed endometrium remained in the uterus to permit study and classification.

Endometrial polyps were present in 10 cases (17 per cent) and adenomyosis of varying degree was diagnosed 13 times (21 per cent). Others have remarked on the relative frequency with which these two conditions are found in senile uteri. The incidence of polyps, for example, is two and one-half times as great as that found by Henriksen (1941) among a large group of younger women, selected because of the complaint of abnormal vaginal bleeding.

Epithelium. The surface epithelium consisted of a single layer of low cuboidal cells arranged in a fairly straight or slightly undulating line. Here and there it could be seen dipping down slightly into the stroma (Fig 1), but in only rare instances could any connection be demonstrated between the glands and the surface epithelium. This observation is believed to be of importance in the interpretation of the cysts, described later.

The endometrial glands varied greatly in size, shape, and number. In some cases only an occasional small round gland was visible in the remnant of mucosa which covered the myometrium (Fig 1). In others the endometrium was somewhat thicker and contained a greater number of glands, some slightly larger, and some slightly branched (Fig 2). Occasional mitotic figures could be demonstrated even in some atrophic endometria such as this. It is questionable whether mitotic figures in this tissue are necessarily indicative of specific estrogenic stimulation, as several previous authors have assumed.

An interesting and not uncommon variant in the endometrial pattern consisted of atypi-

cal, irregularly branched and dilated glands (Fig 3). These bore no special relation to the other glands nor were they confined to any specific location. Their lumens commonly contained amorphous material as did the more typically cystic glands, herein described.

In contrast to the findings in previous studies, particularly that of Novak and Richardson, the present material has not revealed hyperplasia as a normal manifestation of the senile endometrium. This diagnosis was made in only 3 cases. When the clinical histories of these patients were later reviewed it was found that 2 of them had received estrogenic therapy for about 3 weeks immediately preceding operation. One, aged 61 years, had been taking stilbestrol by mouth (Fig 4), the other, aged 57 years, had received her estrogen in the form of stilbestrol vaginal suppositories daily (Fig 5). The third patient with endometrial hyperplasia (Fig 6), aged 61 years, had a small tumor in the left adnexal region. This was palpated by the attending gynecologist who had examined the patient prior to her admission to the hospital, and the suspicion of a granulosa cell tumor was recorded. Unfortunately the ovaries were not investigated at operation. In 2 of the 3 cases of hyperplasia, therefore, a definite exogenous source of stimulation was present and in the third instance the presumption is strong that a functional ovarian tumor was responsible. *In not a single case of the present series was spontaneous endometrial hyperplasia encountered.*

Cystic glands, varying in size and number, constituted one of the most consistent as well as one of the most interesting findings in the present study. These cystic structures were seen in routine sections of 43 of the 60 uteri (72 per cent).

Novak and Richardson, in their paper of 1941, redirected attention to the cystic glands of the senile endometrium, clearly demonstrated these structures in photomicrographs, and, impressed with their Swiss cheese pattern, interpreted them as evidence of hyperplasia. The present material and theirs are not strictly comparable, since many of their patients complained of bleeding, whereas the uteri in the present study were all presumably normal save for their descensus. This dif-

ference will help explain our failure to confirm the high degree of hyperplasia reported by Novak and Richardson. Of probably greater importance, however, is the alternative interpretation which we are inclined to give the large cystic glands which have been observed in the majority of our cases and which appear to be identical with the glands in the specimens classified by Novak and Richardson as "retrogressive hyperplasia."

Study of our material has led to the conclusion that the cystic structures in the senile endometrium are indeed retention cysts, as some of the older gynecological pathologists thought them to be. These cysts form, it is believed, following the occlusion of the gland openings which results from the atrophy of their lining epithelium. The stimulus to dilatation of the blind pouches thus formed comes from the desquamating lining cells. The early stages of this process can be visualized in Figures 7 and 8. As the gland cells are replaced and cast off into the lumens the cysts enlarge. The cellular nature of the cyst contents becomes less apparent as autolysis and liquefaction occur (Fig 9). Finally the desquamated material is reduced to an amorphous mass (Fig 10). Sometimes this appears granular, sometimes homogenous, and takes only a faint pink stain with hematoxylin and eosin. Subsequent stages, showing progressive enlargement of the cysts, are shown in Figures 11 to 15. Although they may occur at any level

of the endometrium, the cysts have a predilection for the superficial stratum, where they are covered by the very thinnest layer of surface epithelium. Figure 12 shows such a cyst separated from the uterine cavity by only a single layer of cells.

We visualize these structures, therefore, as cystic dilatations of endometrial glands resulting from mechanical obstruction of their mouths and desquamation or secretion into their lumens. In this respect they are quite analogous to the nabothian cysts of the cervix. Their similarity to the glands of a hyperplastic endometrium is only superficial, the chief characteristic common to both types being the Swiss cheese pattern presented by the cystic glands of varying size. The epithelium of the postmenopausal cyst is flat and inactive looking, mitotic figures rare, in contrast with the histologic picture of the cystic hyperplasia seen in younger women. Important differences exist too in the stroma, herein described. The cystic endometrial glands of postmenopausal women quite commonly attain a size several times that reached by the glands seen in the cystic hyperplasia of younger women. One of the larger glands in the present series is shown in Figure 15. It is difficult to reconcile this observation with the thesis of Novak and Richardson that these structures are the remnants of pre-existing typical cystic hyperplasia. It seems necessary to accept the idea of a progressive dilatation of the glands, be-

Fig 9 Endometrium of patient, aged 85 years, 35 years after the menopause. Glands are moderately dilated and contain amorphous material, cellular detail of which has largely been lost. Evidence of desquamation can be seen in the lining of the upper gland.

Fig 10 Endometrium of patient, aged 58 years, 8 years after the menopause. Cystic gland, filled with amorphous debris, occupies entire thickness of endometrium.

yond any size ever attained during the reproductive years, when the mouths of the glands are open. The histologic structure suggests a distention rather than an active proliferation.

Polyyps Cystically dilated glands are especially common in the endometrial polyyps which occur in postmenopausal women (Fig 16). This association is of interest from three points of view. First, the Swiss cheese pattern has frequently been the basis for the erroneous diagnosis of endometrial hyperplasia, especially when the pathological report has depended on the examination of curettings. Kottmeier has recently established criteria for the differentiation of endometrial polyyps and hyperplasia in curettings with the aim of minimizing this error. Second, rupture of the superficial cysts is the probable mechanism of the uterine bleeding which is commonly seen in patients with endometrial polyyps. The thin walled veins of the senile uterus, described later, are particularly vulnerable to such an accident because of their location just below the surface epithelium. Finally it seems more than possible that the cystic glands themselves are an important factor in the pathogenesis of postmenopausal endometrial polyyps, since these growths consist in large part of such cysts and their surrounding stroma. This thesis would help explain the high incidence of endometrial polyyps in postmenopausal uteri.

Stroma The stroma of the postmenopausal endometrium differs markedly from that of the cyclic mucosa of younger women. Most striking is the difference in staining characteristics. In contrast to the deeply basophilic color which the youthful endometrial stroma assumes with the usual hematoxylin and eosin stains, the senile mucosa is predominantly eosinophilic, but considerable individual variation exists in this respect. This change results from the altered histologic composition of the tissue. The lymphoid elements of the stroma are replaced after the menopause by a less cellular, more fibrous structure. The remaining cells are predominantly spindle-shaped fibrocytes, and the relatively more abundant matrix becomes homogeneous and hyalinized, especially near the surface (Figs 2 and 17). Focal accumulations of round cells may persist here and there for many years after the menopause, but they form a quite inconspicuous part of the histologic pattern.

Blood vessels The specialized arterial apparatus which supplies the stratum functionalis of the human endometrium and is characterized by coiled vessels atrophies after the menopause. This atrophy sets in promptly and proceeds rapidly, so that in the present material routine sections revealed no structures which could be recognized as spiral arterioles. It is quite likely that the disappearance of these vessels is related to the diminution in circulating estrogen. Okkels and Engle (1938) concluded that the integrity of the coiled arteries of the

Fig 11 Endometrium of patient, aged 62 years, 12 years after the menopause, showing large cystic glands lined with flattened epithelium

Fig 12 Endometrium of patient, aged 66 years, 23 years after the menopause. Note displacement of surface epithelium by greatly enlarged cystic gland

macaque's endometrium depended upon this hormone, since "fibroelastoid degeneration" occurred in spayed animals and restitution could be produced by treatment with estrone. Spiral arteries have been described recently in the ovary, too, and there is some evidence that here as well the coiled vessels depend on the trophic action of estrogen (Delson, Lubin, and Reynolds, 1948).

Perhaps of greater practical importance is the condition of the veins in the senile uteri, for it is probably from these vessels that most spontaneous bleeding occurs. In a fair proportion of the specimens comprising this series thin-walled veins, filled with blood, coursed through extremely superficial layers of the

endometrium, being separated from the uterine cavity in some instances by only one or two layers of cells (Figs 17 and 18). This arrangement will doubtless explain some of the not infrequent cases of vaginal bleeding in which curettage fails to reveal the cause. The fortuitous location of such a vein superficial to an expanding cystic gland subjects the vessel to the possibility of trauma, especially should the cyst rupture. This is suggested as a common mechanism of hemorrhage from post-menopausal endometrial polyps.

One might suspect the prominence of superficial veins in the present material to be a secondary effect of the uterine descensus, from which all the patients suffered to a varying degree. While recognizing such a possibility,

Fig 13 Endometrium of patient, aged 65 years, 15 years after the menopause. Enlarged cystic gland has displaced surface epithelium. Compare with Figure 12

we believe it relatively unimportant, since a recent study of postmenopausal women without uterine descensus also describes circulatory modifications in the form of vascular dilatation and telangiectasia in the endometrium (Gianaroli, 1948)

DISCUSSION

The present study differs fundamentally from previous ones on the postmenopausal endometrium because of the different basis for selection of material. Others have chosen their specimens from the postmenopausal endometriums of their pathological laboratories without discrimination because of the patient's complaint. A large proportion of such pa-

tients suffered from postmenopausal bleeding, which was the reason for hysterectomy or curettage. It is apparent that by failing to select their material these previous authors actually obtained a rather highly selected series of endometriums, which would be expected to show a relatively high incidence of abnormality. We have attempted to circumvent this obstacle and to obtain endometriums representative of the normal by choosing our specimens from a group of patients free of bleeding and without evident uterine disease. Furthermore, the entire endometrium as obtained by hysterectomy offers advantages over the fragments of tissue obtained by curettage, as in some previous studies. The principal problems associated with examination of post-

Fig 18 Endometrium of patient, aged 76 years, 16 years after the menopause. Arrow points to superficial vein just beneath (denuded) surface epithelium

menopausal curettings consist of the impossibility of making a diagnosis in the significant group in which no tissue is obtained, and the difficulties sometimes encountered in interpreting fragmented tissue, particularly in differentiating between an endometrial polyp and hyperplasia.

Finally the different criteria used for the diagnosis of hyperplasia undoubtedly account in large measure for our failure to corroborate the high incidence of hyperplasia previously reported in postmenopausal uteri, particularly by Novak and Richardson. Not all would agree, for example, with the diagnosis of active hyperplasia given to some of the specimens illustrated in their paper, and to the cystic glands which they have interpreted as retrogressive hyperplasia we would accord the alternative interpretation of glandular dilatation resulting from mechanical obstruction of the gland outlets. It is probably because of more exacting criteria used for hyperplasia that Schiffmann (1929) diagnosed this condition in only 1 of 59 women with postmenopausal bleeding.

Our observations indicate that atrophy is the normal condition of the asymptomatic postmenopausal endometrium. The hyperplasia present in 3 cases could be ascribed in each to an actual or presumed abnormal source of estrogenic stimulation. From a purely theoretical point of view it is difficult to see how this could be otherwise, if our current notions concerning the etiology of endometrial hyperplasia are correct. Although women may excrete small amounts of estrogen for several years after their cessation of menstruation, and evidence of estrogenic activity, even of periodicity, may be detected in vaginal smears long after the menopause (Papanicolaou, 1933, Kernodle and Cuyler, 1948), the quantities of available hormone are far below the levels usually associated with proliferation of the genital tissues. This point is attested by the atrophy of the vulval and vaginal tissues and the decrease in bulk of the uterus consistently associated with normal aging.

Castration in the rhesus monkey commonly leads to focal hyperplasia in the mammary gland with the development of discrete nodules in the breast (Speert, 1940), and in cer-

tain strains of mice proliferative changes occur in the adrenal cortex as well following removal of the ovaries (Fekete, Woolley, and Little, 1941). The precise hormonal mechanisms for these atypical growth processes are not understood. This study provides no basis for the belief that the endometrium is a common site for any similar hyperplastic response to the withdrawal of ovarian support. Failure to demonstrate endometrial hyperplasia in the present series of normal specimens leads to the belief that this finding is an abnormal one in the postmenopausal woman.

SUMMARY

- 1 A histologic study is reported of 60 normal uteri removed from women aged 50 to 85 years and 2 to 35 years beyond the menopause.
- 2 Endometrial polyps were present in 10 cases (17 per cent) and adenomyosis in 13 (21 per cent).
- 3 Cystically dilated glands were present in routine sections of 43 of the uteri (72 per cent). The pathogenesis of these structures, which are believed to be retention cysts, is discussed.
- 4 Changes in the stroma consisted chiefly of fibrosis and hyalinization, especially near the surface.
- 5 The spiral arteriolar apparatus could not be demonstrated, but thin-walled veins were prominent just under the surface epithelium.
- 6 True hyperplasia was present in only 3 uteri, at least 2 of which had been subjected to abnormal sources of estrogenic stimulation. Hyperplasia appears to be an abnormal finding in the postmenopausal endometrium.
- 7 An explanation is suggested for certain cases of idiopathic postmenopausal bleeding, and for the common association of bleeding with endometrial polyps.

TREATMENT OF SLIPPING OF THE UPPER FEMORAL EPIPHYSIS

A Study of the Results of 42 Cases

CLARENCE H HEYMAN, M D, F A C S, Cleveland, Ohio

SLIPPING of the upper femoral epiphysis occurs in different forms and degrees. There is the early potential pre-slipping stage with little or no displacement, manifested by comparatively mild symptoms. Deformity may then increase abruptly following mild trauma. This is known as the acute slip with severe displacement of the epiphysis causing immediate and marked disability. More commonly, however, the displacement may progress gradually or intermittently known as the chronic slipping with gradually increasing disability. Bony union between the epiphysis and the neck of the femur eventually occurs with a greater or lesser deformity and disability. There is no sharply defined time to mark the final stage of deformity when union has occurred to such a degree that it becomes impossible to alter the position of the head in relation to the neck without osteotomy.

We are concerned in this study with the treatment of the slowly progressing or chronic form of slipping rather than with the acute slip. During this still formative stage in the development of treatment adaptable to the majority of cases, surgeons of comparable experience practice different methods. These results show why some methods are in favor, and others are in disfavor, in the clinic where these patients were treated and where as in all hospitals the facilities and limitations must be evaluated by every surgeon.

In this group of 42 cases, 2 years or more have elapsed since the cessation of treatment, unless a poor result is already present or may obviously be predicted. The results are classified separately as to the clinical or functional result, and the anatomical or structural result as revealed by the roentgenogram. It is interesting that there is often a discrepancy in the classification of the result according to these two criteria.

Fig 1 a, above W L Extremely overweight boy, 16 years old Duration of symptoms 8 months Had severe limp, pain, and very little motion at the hip Treated by manipulation and cast b, Four and one half years later He has no pain, no limp, and no limitation of motion The head of the femur is moderately deformed, but is otherwise good

Fig 2 a, above R C Markedly overweight boy, 14 years old Duration of symptoms 6 months Had severe limp and external rotation deformity Treated by manipulation and cast b, Five and one half years later Although the epiphysis was not altered in position by manipulation, the head of the femur looks good He has normal motion and function

All of these patients had a gradual onset of symptoms and a slowly progressing disability, sometimes to a marked degree, and the epiphyseal plate was still open The duration of symptoms varied from 2 to 9 months, except for 2 patients who had symptoms for 2 years The ages at the time they came for treatment varied from 10 years to 18 years The average age was 14 years All complained of pain, some moderate and some severe All patients limped and had limitation of motion, some moderate and some marked Some had marked displacement of the epiphysis, and others had only a minimal slip Thirty-five were males, 7 were females Thirty-seven were unilateral slips, 5 were bilateral Twenty-three were of excessive weight suggesting a glandular dyscrasia, and 19 were normal in these respects It was noticed, however, that some of the children who appeared to be of normal weight and development at the time of treatment became overweight and developed the appearances or stigmas of glandular dyscrasia as they became older

METHODS OF TREATMENT

Manipulation under anesthesia followed by fixation in a plaster spica with the extremity

widely abducted and internally rotated was the method of treatment in 21 of the 42 cases The method commonly used was that of Leadbetter to reduce fracture of the neck of the femur traction with the hip at right angled flexion, internal rotation, and then with the hip brought down in internal rotation and wide abduction Considerable force was used when it was thought necessary Osteotomy through the neck of the femur or through the epiphyseal plate, with fixation by means of a nail and plaster spica was done in 3 cases, osteotomy with fixation in plaster only was done in 5 cases Simply a removal of the prominent angular portion of bone obstructing motion at the anterosuperior aspect of the neck of the femur, without osteotomy and with no postoperative fixation, was done in 3 cases Fusion of the epiphysis by an open and direct approach, without the insertion of a nail or postoperative fixation, was done in 10 cases These had comparatively slight displacements and were not manipulated

RESULTS OF MANIPULATION AND PLASTER SPICA

Good to excellent clinical results were obtained in 17, or 81 per cent, of the cases treat-

Fig 3 a, above. J R Girl, 11 years old. Duration of symptoms 3 months. She had severe disability. Treated by manipulation and cast. b, Three years later. She has a normal hip.

Fig 4 a, above. H H Boy, 14 years old. Had a gradual onset of symptoms beginning 7 weeks before, but the roentgenogram may be suggestive of an acute slip. Manipulation failed to improve position, nevertheless, he was treated by a spica cast with the extremity in wide abduction. b, Five years later. Motions normal except internal rotation is moderately limited. Clinical result is good, roentgenological result is fair.

ed by manipulation. It was found that ability to improve position according to the roentgenogram was not directly dependent upon the duration of symptoms. This, of course, would not apply to the sudden and acute slips with a marked displacement which are not included in this article. Considerable improvement toward restoration of anatomical position was possible in cases with a duration of symptoms varying from 1 to 9 months, while little or no success in improving position was had in other cases with a duration of symptoms varying from 2 to 6 months. This greatly depended upon the width of the epiphyseal plate, or absorption of bone adjacent to it, at the time of treatment.

It was a common observation that even though manipulation in the cases of longer standing sometimes failed to alter appreciably the position of the head on the neck of the femur, the clinical improvement was generally marked. Pain disappeared in all cases, and there was a decided improvement in the ranges of motion. Manipulation with cast appears to bring about a fairly prompt fusion of the epiphysis, and perhaps this may be a cause for the cessation of pain and muscle spasm. Contracture, rather than bony displacement, may be a major factor in many cases causing clinical deformity and limitation of motion. There

is no other way to explain the correction of external rotation deformity and greatly limited abduction in the cases in which position of the epiphysis was not much improved. Release from contracture of the adductor and external rotator muscles, or more likely from contracture of the joint capsule or other fibrous structures, is accomplished by manipulation followed by maintaining the extremity in abduction and internal rotation. It is unlikely that rest alone or abstention from weight bearing would be equally effective. Treatment by traction, which may be effective in the acute slip, was tried in only 1 case. This did not result in any improvement in motion after 6 weeks.

The criterion for estimation of the result on the roentgenogram is not solely the position of the head on the neck. Of greater importance are the structure of the bone, the width of the joint space and smoothness of the articular surfaces. A good viable head and a good articular surface are more to be desired than a normal anatomical relationship with aseptic necrosis. On the basis of these criteria, the roentgenological result was good in 67 per cent of the cases in which manipulation was carried out. Twenty-eight per cent are classified as

Fig 1 a, above W L Extremely overweight boy, 16 years old Duration of symptoms 8 months Had severe limp, pain, and very little motion at the hip Treated by manipulation and cast b, Four and one half years later He has no pain, no limp, and no limitation of motion The head of the femur is moderately deformed, but is otherwise good

It was a common observation that even though manipulation in the cases of longer standing sometimes failed to alter appreciably the position of the head on the neck of the femur, the clinical improvement was generally marked Pain disappeared in all cases, and there was a decided improvement in the ranges of motion Manipulation with cast appears to bring about a fairly prompt fusion of the epiphysis, and perhaps this may be a cause for the cessation of pain and muscle spasm Contracture, rather than bony displacement, may be a major factor in many cases causing clinical deformity and limitation of motion There

is no other way to explain the correction of external rotation deformity and greatly limited abduction in the cases in which position of the epiphysis was not much improved Release from contracture of the adductor and external rotator muscles, or more likely from contracture of the joint capsule or other fibrous structures, is accomplished by manipulation followed by maintaining the extremity in abduction and internal rotation It is unlikely that rest alone or abstention from weight bearing would be equally effective Treatment by traction, which may be effective in the acute slip, was tried in only 1 case This did not result in any improvement in motion after 6 weeks

The criterion for estimation of the result on the roentgenogram is not solely the position of the head on the neck Of greater importance are the structure of the bone, the width of the joint space and smoothness of the articular surfaces A good viable head and a good articular surface are more to be desired than a normal anatomical relationship with aseptic necrosis On the basis of these criteria, the roentgenological result was good in 67 per cent of the cases in which manipulation was carried out Twenty-eight per cent are classified as

Fig 5 a, above P S Girl, 12 years old Duration of symptoms 4 months Only a minimal slip at the right hip Treated by open fusion of the epiphysis b, Ten years later She has normal function and roentgenological result is practically normal

Fig 6 a, above H H Boy, 15 years old Duration of symptoms 3 months No appreciable slip, but physical findings were typical of slipping of epiphysis Treated by open fusion of epiphysis b, 2 1/2 years later Function normal Head may be slightly underdeveloped, but otherwise normal

having a fair roentgenological result only because of faulty position of the head on the neck In only 1 case is there a poor roentgenological result (5 per cent) with a poor bone structure in addition to deformity This was the case of a boy, 18 years old, who had symptoms for 2 years before treatment

RESULTS OF CERVICAL OSTEOTOMY

By cervical osteotomy is meant open reduction by osteotomy through the epiphyseal plate or a cuneiform osteotomy through the neck It is to be emphasized that these are the results of one surgeon only There were only 8 cases of cervical osteotomy to correct deformity, for it was soon found that the results were not good even after the patient was subjected to this major operation More or less aseptic necrosis with degenerative changes resulted in 7 of the 8 cases A good roentgenological result was obtained in only 1, and this patient has only 45 degrees of flexion, and rotation is greatly limited The only poor results, both clinically and roentgenologically, have been in those patients treated by cervical osteotomy The results of manipulation and cast in the case of longer standing, even though not much improvement in anatomical position has been obtained, have been so much better that the

writer now does a cervical osteotomy only in unusual conditions

REMOVAL OF THE BONY OBSTRUCTION TO MOTION

The first operation of this nature was done in 1942 in the case of a marked displacement of 5 months' duration and with a marked limitation of motion Preparations were made for cervical osteotomy and nailing, but at operation it appeared that bony union was so secure that we withheld from osteotomy Since limitation of motion was seen to be caused by an impingement of the angular prominence of bone at the anterosuperior aspect of the neck against the rim of the acetabulum, it was decided to chisel off the obstruction at the neck of the femur Good motion resulted immediately He was kept in bed 1 week afterward and progressed so well that he was then allowed crutches and weight bearing according to his own inclinations He was soon bearing full weight on the leg, and retained most of the greatly improved range of motion gained at operation Encouraged by this success, 2 more operations were done with similar satisfaction Another patient with bilateral involvement, too recent to be included in this report, obtained striking improvement of motion when

Fig 7 a, above R C Boy, 15 years old Duration of symptoms 5 months He had severe pain and was unable to bear any weight on the leg There was very little motion even under anesthesia Operative exposure was made for osteotomy and nailing, but only the angular bony prominence at the neck was removed He was kept in bed 1 week postoperatively and there was a rapid relief of symptoms See text b, Five years later He has no pain, practically no limp, and motion is only moderately limited Clinical result is good, roentgenological result is fair

Fig 8 a, above S C Girl, 11 years old Duration of symptoms 10 months Treated by osteotomy and nail which was removed later because of stiffness and pain b, Four years later She has pain and stiffness The clinical and roentgen results are poor

6 weeks of traction in bed beforehand had no effect These patients have good hip joint spaces and no roentgenological evidence of aseptic necrosis Since the roentgenograms show, of course, the deformity as before, these cases are classified as having only fair roentgenological results It is intended to gain further experience with this conservative method of treatment¹

EPIPHYSEAL FUSION

Since a direct operative approach to bring about a prompt fusion of the epiphysis has proved to be reliable in arrests of growth, an adaptation of this method for fusion was done in 10 cases presenting only a minimal displacement It was thought that a graft of bone across the epiphyseal plate would be more reliable in bringing about a prompt fusion than the introduction of a Smith-Petersen nail It was also taken into consideration that nailing

a capital epiphysis requires considerably more precision, particularly in the exact length of the nail and in centering, than is required in nailing a fracture of the neck of the femur Multiple drilling was done in 1 case only This epiphysis ultimately fused after many months of nonweight-bearing protection, and there is a good result

Description of the operation of fusion Exposure of the anterosuperior aspect of the neck of the femur is made through a Smith-Petersen approach The capsule is incised longitudinally and is reflected only enough to expose the neck at its junction with the head incurring a minimum of disturbance to the blood supply The epiphyseal line is looked

Fig 9 R M Boy, 15 years old Bilateral case treated by a capable surgeon by means of cervical osteotomies and nailing Nails were removed later He has ankylosis of both hips 1 year after operations

¹The writer was not aware that this operation had been done before but, during a recent conversation with Dr L Ramsey Straub of New York, he was told that Dr Royal Whitman referred to it in an article published in the *Medical Record* January 9 1909

for, but may not always be identified. A rectangular section of bony cortex, about 4 centimeters long and 1 centimeter wide, is removed along the long axis of the neck, with care not to disturb the articular surface. This is laid aside to be used later. A small curet or gouge is introduced into the gutter, and by a rotatory motion is forced into the central portion of the head deeply enough to be sure that it passes across the epiphyseal plate. Small pieces of cancellous bone, obtained from the crest of the ilium, are impacted into the depths of the hole which passes into the head of the femur. The piece of bony cortex previously removed is then replaced or may be driven in as a peg. The capsule is sutured, and the wound is closed.

No postoperative fixation is used other than light temporary traction for comfort and restraint. Weight bearing is not permitted until the roentgenogram shows that fusion has occurred, or until progress is well under way toward fusion. Traction, as a rule, is continued for about 6 weeks, followed by ambulation with crutches and only partial weight bearing for another 6 weeks. It was found that pain and muscle spasm rapidly subsided, and there was soon a return to normal passive and active motion. Fusion of the epiphysis occurs in about 3 months after this operation.

RESULT OF EPIPHYSEAL FUSION

Ten operations were done upon 8 patients—2 were bilateral—without manipulation or other treatment. The ages ranged from 13 to 15 years. Both the clinical and roentgenological results are good to excellent in all cases. All have complete relief of symptoms and have practically normal motion and no limp, and the roentgenograms showed a prompt fusion with no increase in displacement over that originally present. There is a normal appearing bony structure and a normal joint space.

SUMMARY OF RESULTS

A clinical result is classified as good when the patient has no disability, no pain, little if any limitation of motion, and no more than a very slight limp, the result is fair when the patient has no pain, but there is a moderate limitation of motion or a moderate limp, the

result is poor when there is pain, or a considerable degree of limitation of motion, or a conspicuous limp. The roentgenological result is classified as good when at most there is only a slight deformity, which would not seem to be important, and no appreciable aseptic necrosis or articular changes, the result is fair when the displacement of the fused head on the neck of the femur is moderate, but there is no appreciable aseptic necrosis or articular changes, the result is poor when there is aseptic necrosis accompanied by narrowing of the joint space and roughening of the articular surfaces.

All of the 10 patients selected for operative fusion of the epiphysis have a good to excellent clinical and a good roentgenological result. Of the 21 patients treated by manipulation and cast—and it is to be considered that all of these cases of considerable displacement were less favorable—17, or 81 per cent, have a good to excellent clinical result, and 14, or 67 per cent, have a good roentgenological result. Only 1 patient has a poor joint space and aseptic necrosis. There were no poor clinical results following manipulation and cast, and most patients have little or no physical disability. Still more important, none has pain. There are no poor roentgenological results following manipulation and cast other than failure to improve anatomical position of the head, except 1 case of an 18 year old boy who had had pain and disability for 2 years. These generally good results of manipulation and cast are in marked contrast to the poor clinical and roentgenological results of treatment by cervical osteotomy. There was only 1 good clinical result and 1 good roentgenological result in the 8 cases treated by cervical osteotomy. These were not in the same patient. Removal of the angular bony obstruction to motion greatly improved function in each of 3 cases, and the joint space and bony structure look good.

These unanticipated results of manipulation are deserving of further comment. It seems that there has been an almost unanimous opinion expressed by recent writers that manipulation must be avoided, and those who confess to manipulation expressly caution that it must be gentle to avoid disturbances to the

circulation of the head of the femur or damage to the hip joint. This opinion is not confirmed, for these patients have no aseptic necrosis up to the present time. It was formerly contended that manipulation per se caused the unfavorable late changes of the head of the femur following reduction of congenital dislocation of the hip, and it is also likely that manipulation itself in slipping epiphysis does not cause the joint damage ascribed to it. Perhaps the failure to obtain better clinical results in the slowly progressing case of longer standing is because manipulation had been so gentle that nothing in the way of improvement could be accomplished. In the hands of the writer and of most orthopedic surgeons, manipulation is far less likely to be attendant with damage to the hip than in the procedure of cervical osteotomy and nailing which is also a difficult operation even in the hands of the most experienced and skilled surgeons. The choice of the method of treatment must be a matter for the individual who is governed by his own abilities and limitations.

CONCLUSIONS

These results, analyzed separately and conjointly according to the functional and roentgenological results, have determined the writer's present practice in the treatment of slipping of the femoral epiphysis. They are regarded as intermediate results only. Final results cannot be determined until later in life.

Operative fusion by means of a bone graft across the epiphyseal plate is the method of choice during the early stage when there is no displacement to more than a slight degree. This method is reliable to bring about prompt fusion of the epiphysis, it shortens the period of disability, and prevents further displacement.

This method of manipulation and cast remains preferable to osteotomy in the still active stage when displacement has progressed to a considerable degree. Motion may be restored in most cases to a near normal range, and the limp practically eliminated, even though not much improvement in the anatomical position of the head is obtained. Aseptic necrosis is rare. The small number of patients treated by cervical osteotomy was sufficiently large to convince the writer that, in his hands, the results are generally poor. The manipulation and cast procedure is a safe method of treatment, patients are not made worse by it. Cervical osteotomy, on the other hand, may give a good result, but one must realize that this is a difficult operation to do well and that aseptic necrosis is a complication of intracapsular fracture of the neck of the femur.

Treatment of the late or residual stage of deformity when fusion has already occurred depends on the amount of disability. It is better to accept some limitation of motion and limp without pain than to strive for free motion with probable pain or even more stiffness. Motion in these cases of long standing can be improved only by some form of osteoplastic operation. While subtrochanteric osteotomy may correct external rotation and adduction deformity, it would not seem likely to improve flexion of the hip. No settled conclusion can be reached on the basis of 3 cases, but simple removal of the bony obstruction to motion at the anterosuperior aspect of the neck of the femur gave good functional results, and there is no roentgenological evidence of disturbance of the blood supply to the head of the femur. If further experience confirms this result, we shall have an important conservative method of treating the case of long standing with a fixed and disabling deformity.

Fig 4 Ulcer following laminectomy and 5 full courses of irradiation for spinal cord tumor a, Initial defect, note vertebral spines (June 1941) b, Defect after multiple conservative débridements and zinc peroxide treatment (January 1943) c, Final removal of necrotic tissue and start of plastic procedure (July 1944) d, Completion of closure Under fluorescein study all of Zone 1 could have been outlined and removed at first operation

weakly fluorescent area corresponding to the partially devitalized skin and subcutaneous tissue classified as Zone 2, and, in many ulcers, extending deeply to the muscle and bone (Fig 1) The fluorescence gradually increases away from the lesion until normal is reached Sections of these ulcers in the operating room reveal a deep penetration of the completely devitalized Zone 1, and a similar deeply penetrating surrounding area of partially devitalized Zone 2 (Fig 2)

From a preliminary superficial study the repair can be planned and the size of flaps estimated After local control of the infection is attempted as outlined in a previous paper (3), the surgical toilet of the wound is carried out in the operating room The anesthetist injects the fluorescein solution, the room is darkened, and the area is viewed under the filtered ultraviolet light In the case of superficial ulcers, the zones are estimated and are marked with indelible pencil, the lights turned

Fig 5 Case 3 Reconstruction of left temporal postirradiation ulcer with residual carcinoma extending to lateral wall of orbit and upper lid Fluorescein studies permitted the major portion of the reconstruction to be carried out in less than 2 months, despite osteoradionecrosis a, Postirradiation defect with extension to upper lid and lateral wall of orbit b, After excision of soft tissue and bone extension and implantation of flap to prevent protrusion of orbital contents c, Excision of radionecrotic area and implantation of distal end of tube into area of good vascularity d, Tube opened and defect closed

on, and the excision carried out. For deeply devitalized lesions, frequent observations under filtered ultraviolet light are made during the course of the operation. Those portions showing complete devitalization by a total absence of yellow gold fluorescence are excised in extent to normal fluorescence in skin and subcutaneous tissue and in depth to partial fluorescence in muscle, etc., unless the area is sufficiently superficial, or small, to warrant excision of all damaged tissue. In other words, all of Zone 1 should be removed and as much of Zone 2 as possible unless vital structures are involved. In the repair, the principle of revascularization is brought into play and from a normally fluorescent area a flap is bridged over the saucerized defect to another normal area, and, when healing is complete, the tubed flap is opened and approximated laterally to the normally fluorescent sides. Throughout the repair, the optimum time for transference of pedicled flaps is estimated by fluorescein, as outlined by Lange (5).

Out of a group of several hundred postirradiation ulcers requiring active surgical treatment during the past 10 years, 3 characteristic cases are presented to show the advantages of diagnostic fluorescein.

The first is a deep necrotic ulcer (Fig. 3) of the scalp. When, after 2 delays, a flap was swung to this area, the blood supply was inadequate, and the distal end died (Fig. 3b). Fluorescein would have outlined this zone of relative avascularity and obviated implantation in a devitalized area.

The second series of pictures shows the result of 5 full courses of irradiation for a post-

laminectomized spinal cord tumor. Because of the lack of appreciation of the extent of the completely avascular area, the final result was not accomplished until after 3 years of work. Under fluorescein study, all of Zone 1 could have been outlined and removed at the first operation.

The last series of pictures shows the comparative rapidity with which knowledge of the vascularity as outlined by fluorescein can speed up the procedure. The main structural correction was carried out in a matter of months.

SUMMARY

Fluorescein as an agent for determining the residual vascularity and extent of deep radionecrotic lesions places on a more objective plane the demarcation of devitalized and partially devitalized tissues. Its use enables the surgeon to determine the actual extent, levels, and degree of revascularization. The incidence of failure, as well as the time necessary for these multiple staged procedures, is reduced.

THE USE OF URECHOLINE IN THE PREVENTION OF POSTOPERATIVE DISTENTION

CLARENCE E STAFFORD, M D, F A C S, ARTHUR I KUGEL, M D, and
ALEXANDER DEDERER, M D, Los Angeles, California

ABDOMINAL distention is a common postoperative problem that distresses both the surgeon and the patient. Our present concept, however, of the physiology of the autonomic nervous system in relation to intestinal atony has done much toward progress in the treatment of this important complication. Following every abdominal operation and many surgical procedures in other parts of the body, there is apparently depression of the parasympathetic nervous system affecting the gastrointestinal tract. This is seen in varying amounts and is attributed to the effects of such factors as trauma of surgery, shock, anesthetic agents, sedative and narcotic drugs.

During recent years, an increasing number of drugs which affect the parasympathetic system have been used for the relief of postoperative distention (2, 5, 8). These parasympathetic agents can be divided into 2 groups—the choline esters and physostigmine with its related synthetic compounds. The choline esters such as acetylcholine, mecholyl and doryl act as chemical mediators in stimulating the receptor cells of smooth muscle. The effect of acetylcholine, however, is rapidly neutralized by the hydrolytic action of cholinesterase, an enzyme present in blood and tissues. The physostigmine group which includes the synthetic compound, prostigmine, does not act as a chemical mediator and has no direct action on smooth muscle. It inhibits cholinesterase and thus allows acetylcholine, which is produced in the body, to give more prolonged and constant action (1).

These cholinergic drugs have given good results in the treatment of postoperative intestinal distention, but have some disadvantages.

From the Department of Surgery, College of Medical Evangelists School of Medicine, and the Surgical Service, White Memorial Hospital.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Los Angeles, October 18 to 22, 1948.

(2) In searching the field of synthetic choline esters for suitable therapeutic products for postoperative distention, a major objective has been to find a stable drug with a constant action in the body. A second objective has been to find derivatives that are free from toxic symptoms when used in clinical dosage. Finally, attempts have been made to find drugs which would have a selective effect on smooth muscle of the gastrointestinal tract and not on other structures such as the vascular and respiratory systems.

Recent attention has been directed toward urecholine (the urethane of beta-methylcholine-chloride) because of its effect in stimulating gastric motility after vagus resection for peptic ulcer (3, 4, 7). This choline derivative has a parasympathomimetic action but is not destroyed by cholinesterase as is acetylcholine and mecholyl, and it has no undesirable nicotinic action as does doryl (8). When administered in therapeutic dosage sublingually, orally or subcutaneously, it has little or no effect upon heart rate, blood pressure, or peripheral circulation of normal human subjects. However, it increases peristalsis, and stimulates micturition and defecation (8). When the drug is given intramuscularly or intravenously, it loses its selective action on the gastrointestinal tract and may produce a drop in blood pressure with circulatory collapse. These effects may be abolished by prompt intravenous injection of atropine.

Because of these pharmacological effects of urecholine in producing gastrointestinal stimulation, it appeared to be a possible remedy for intestinal atony, the basis of postoperative distention. The clinical value of the drug was therefore investigated to determine whether its administration to patients would prove to be an effective method of overcoming postoperative distention with a minimum of side effects.

METHODS AND MATERIALS

Observations were made on 100 patients following major surgical procedures, including hernioplasty, appendectomy, hysterectomy, cholecystectomy, and gastrectomy. Urecholine in dosage of 10 milligrams was given routinely by sublingual route, 3 times daily beginning the day following surgery. Another 100 patients, following similar types of surgery, were observed as controls. This group received no routine prophylactic measures to prevent gas discomfort. In both groups, the patients were classified as (1) those who had no evidence of abdominal distention and required no therapy, (2) those who had definite gas discomfort and abdominal distention and required routine hot packs and special enemas.

Further observation was made on the use of urecholine when administered subcutaneously in doses of 5 milligrams. This was given to some of the patients in addition to the oral medication, when severe gaseous distention was present. In every case, the nurse giving the injection was cautioned to avoid the intramuscular route of administration in an effort to decrease the incidence of untoward side effects.

RESULTS

In the control group, 28 per cent of the patients had no evidence of abdominal distention, while in the urecholine treated group, 45 per cent of the patients were apparently free from abdominal distention. No undesirable side effects were noted in any of the patients who received the sublingual administration of the drug although the dosage was increased to 20 milligrams in some cases.

When urecholine was administered subcutaneously in doses of 5 milligrams there were cases in which the drug produced the passage of flatus and stool as soon as 5 minutes after injection. A few of these patients complained of sweating, nausea, and increase of abdominal cramps although these effects were not marked and usually subsided within 15 to 20 minutes. Sweating was the most frequent of the untoward effects noted.

DISCUSSION

The statistical analysis of this clinical study shows a significant difference in the incidence

of postoperative distention in the urecholine treated group of surgical patients as when compared with the nontreated group. The use of the drug by the sublingual route has the advantage over other drugs of the cholinergic group in the simplicity of administration. The subcutaneous injection of suitable dosage gives a satisfactory therapeutic effect after other methods of treatment have failed to give relief.

The therapeutic effect of urecholine has the disadvantage of other cholinergic drugs in varying considerably with the patient to which it is administered. Because of these variable effects, it is difficult to standardize a routine dosage and in many cases, it must be adjusted for the individual patient in order to obtain a satisfactory result. In a few cases there is no apparent therapeutic effect and in rare instances, the untoward side effects defeat the therapeutic usefulness of the drug.

Certain contraindications to the use of this drug should be noted. Urecholine, like other choline esters, may exert a bronchoconstrictor effect and therefore should be used with extreme caution in cases with asthma or history of allergy. The drug should not be used in the presence of acute inflammatory lesions of the gastrointestinal tract or associated peritonitis where the stimulation of peristalsis may spread the infection present. In this series of cases the drug was not used following large bowel surgery or when peritonitis from any cause was present.

The results of this study would seem to indicate that the routine use of urecholine in the care of the postsurgical patient has an effect in reducing the incidence of abdominal distention with a minimum of undesirable side effects.

SUMMARY

1 Abdominal distention is a common postoperative problem. In a series of 100 control cases, 72 per cent of the patients complained of moderate or severe pain due to gas distention.

2 The pharmacological effects of urecholine indicate that this is a suitable drug to use in the treatment of postoperative distention.

3 Toxic reactions following the use of urecholine may be prevented or controlled by using specific precautions

4 Clinical observations made on 100 post-surgical patients when urecholine was used, demonstrate a definite decrease in the incidence of abdominal distention

A COMPARISON OF PAIN PRODUCED EXPERIMENTALLY IN LOWER ESOPHAGUS, COMMON BILE DUCT, AND UPPER SMALL INTESTINE WITH PAIN EXPERIENCED BY PATIENTS WITH DISEASES OF BILIARY TRACT AND PANCREAS

WILLIAM P CHAPMAN, M D , RUDOLFO HERRERA, M D , and
CHESTER M JONES, M D , Boston, Massachusetts

THE purpose of this investigation has been to compare the localization of pain arising from the biliary tract, lower esophagus, and proximal portion of the small intestine. With few exceptions, lesions in these viscera give rise to discomfort in the upper abdomen, at or near the midline. Yet on the basis of the pain localization alone it is often impossible to tell clinically which structure is involved. During the study of an individual with known biliary tract disease it was noted that balloon distention of the duodenum produced pain apparently identical with that complained of by the patient. This observation raised the question whether pain arising from the bile ducts and the duodenum may have an identical area of localized reference in any given patient. Such a possibility is difficult to demonstrate clinically for various reasons.

- 1 A history of the pain symptom is usually not taken with sufficient care to elucidate slight variations in the localization of pain.

- 2 An evaluation of pain arising from lesions of the lower esophagus, biliary tract, or upper small intestine would necessitate comparing the discomfort in patients usually having only one of these lesions.

- 3 Individual differences in the angle of the costal margin and in the contour of the abdominal wall make pain localization difficult to assess in different patients (7).

From the Surgical and Medical Services of the Massachusetts General Hospital and the Departments of Medicine and Surgery Harvard Medical School.

This study was supported in part by the Josiah Macy, Jr Foundation, New York, New York.

For these reasons we have felt it preferable to study the localization of pain from these viscera by stimulation of each of these structures in the same individual and mapping out the areas of discomfort.

Clinically certain locations have come to be assigned as the area of reference for pain arising from lesions of the lower esophagus, biliary tract, upper small intestine, and pancreas. Disturbances at the lower end of the esophagus such as hiatus hernia or esophageal ulcer usually cause discomfort at the lower end of the sternum or tip of the xiphoid with occasional spread to the back, upper chest, and rarely to the left shoulder or left arm (3, 10, 13). Duodenal ulcer commonly gives rise to pain sharply localized to the midepigastrium over an area about an inch in diameter, and usually nearer the xiphoid than the umbilicus (4). Occasionally, in the case of a perforated posterior wall ulcer adherent to the pancreas, the discomfort may be felt only in the back and has even been known to be present only in the left arm (8, 20). Initially the pain of acute cholecystitis, cholelithiasis, and choledocholithiasis may start in the midepigastrium, remain there, or radiate around the right costal margin to the right scapula. Less commonly the pain may radiate into the left epigastrium or through to the back. In many instances the initial site of pain from the biliary tract may be in the right upper quadrant and very occasionally in the right lower quadrant (5). Pancreatic pain is localized in the epigastrium commonly just left of the midline with occasional reference to left subscapular area (6).

These clinical impressions of the localization of pain arising from these viscera have been substantiated in certain instances by experimental studies. Jones found that distention of the cardiac end of the esophagus produced discomfort in the midline beneath the lower sternum or in the epigastrium just below the xiphoid (11). He also observed that this procedure gave rise in the rare patient to pain in the left postauricular area, the angle of the left jaw, and down the left arm (13). The localization of pain from distention of the duodenum depended somewhat on the area stimulated, the pain being high in the epigastrium on stimulation of the duodenal cap and moving nearer to the umbilicus when the duodenojejunal junction was distended (12). Layne and Bergh, Zollinger, and others found that distention of the gall bladder and common duct produced severe epigastric distress as well as right upper quadrant pain with radiation to the back (15, 16, 22).

In this investigation we have employed these same experimental techniques to test all of these viscera in the same patient. Our observations have been of two kinds

- 1 A comparison of the pain experienced from distention of the lower third of the esophagus, common duct, and upper small intestine (duodenum or jejunum or both areas) in each of our patients

- 2 A comparison of the experimentally induced pain arising from each viscus with the clinical pain noted by a given patient¹

Nine patients were studied, all of whom were convalescing from a common duct exploration. Six patients had biliary tract calculi and 2 had chronic pancreatitis. One patient had had a recurrence of symptoms similar to those existing prior to removal of a stone in the common duct.

METHOD

Experimental pain was produced by distention of the common duct, the cardiac end of the esophagus, and the duodenum or upper jejunum. The esophagus and upper small bowel were stimulated by air inflation of a calibrated

¹Throughout this paper the term clinical pain is used to signify the pain of which the patient complained arising from his lesion as contrasted to the induced or experimental pain elicited by mechanical distention.

balloon of a Miller-Abbott tube. The common duct was distended by two methods (1) was run rapidly through the catheter left the common duct at operation, (2) in 3 patients the common duct was also stimulated by air inflation of a small balloon attached to a ureteral catheter. This catheter was threaded through the intracholedochal tube at operation in such a manner that the balloon was lying freely in the common duct itself. The procedure of balloon distention of the esophagus or duodenum was carried out under fluoroscopic observation so that the position of balloons could at all times be determined. The esophagus, duodenum, or jejunum, air was introduced into the balloon at a uniform rate of from 2 to 4 cubic centimeters per second until the subject reported an uncomfortable sensation. The total amount of air required to produce pain was from 40 to 120 cubic centimeters for the small intestine and from 15 to 30 cubic centimeters for the esophagus. Fluid distention of the common duct consisted of running in sterile saline by sudden elevation of a feeding flask, the amount of pressure being recorded on a water manometer calibrated in inches. When a ureteral catheter was used the balloon was inflated with 8 to 10 cubic centimeters of air which on all occasions was sufficient to produce pain. The similarity of the pain elicited by the ureteral catheter balloon and by distention with saline infusion of the common duct together with the small quantity of fluid displacement required to cause pain by the latter procedure made it seem unlikely that the infusion method was producing discomfort by the escape of fluid into the duodenum. A cholangiogram with hippuran was performed about 48 hours prior to the visceral distention studies to establish the patency of the biliary tree. Although it was possible to increase the intensity of the experimental pain by increasing the balloon distention or the rate of flow of saline through the common duct, this intensification of the stimulus was not attempted routinely. Before the experiments were started, the subjects were asked to state accurately the position and distribution of their clinical pain and to describe its quality and radiation. The experimentally produced pain was recorded

Fig 1 Case 1

TABLE I —PAIN STUDY,
CASE I

	Location	Quality
P Clinical pain	Right sided midabdomen	Deep seated colicky
Experimental pain		
a From common duct	Right-sided midabdomen	Deep seated colicky
b From duodenum	Right sided midabdomen	Deep seated colicky
c From upper jejunum	Right-sided midabdomen	Deep seated colicky
d From lower esophagus	Substernal between 2nd and 3rd interspaces	Deep seated burning

Common duct stimulation and distention of the upper small intestine produced similar pain which was also like the clinical pain. Lower esophageal distention produced pain in a different area.

Fig 2 Case 2

TABLE II —PAIN STUDY
CASE 2

	Location	Quality
P Clinical pain	Right upper quadrant and epigastrium with radiation to left upper quadrant and around the left side to the back	Deep seated, sharp
Experimental pain		
a. From common duct	Same as P but without radiation	Deep seated sharp
b From duodenum	Same as P with radiation	Deep seated, sharp
c. From lower esophagus	Same as P but without radiation	Deep seated burning

Only duodenal stimulation reproduced the clinical pain completely. Common duct distention failed to produce the pain radiation. Lower esophageal stimulation failed to produce either radiation or the quality of discomfort.

Fig 3 Case 3

TABLE III —PAIN STUDY,
CASE 3

	Location	Quality
P Clinical pain	Midepigastria radiating straight through to the back	Deep seated "like knotting of muscles"
Experimental pain		
a From common duct	Same as P with radiation	Same
b From duodenum	Same as P with radiation	Same
c. From upper jejunum	Same as P with radiation	Same
d. From lower esophagus	Same as P without radiation	Same

All areas stimulated gave rise to the same pain which was also similar to the clinical pain except for the lower esophageal stimulation which did not produce radiation of the discomfort straight through to the back.

1 The subject was asked to report any sensation

2 He was asked to outline with one finger the area of any sensation experienced

3 He was asked to describe the quality, intensity, depth, and radiation of the sensation and to compare such sensation with his clinical pain

In each viscus studied, the test was repeated at least three times. Before each experiment the patients were free of clinical pain or other discomfort. Precaution was also taken at all times not to let the patient know which viscus was being stimulated. Aside

from the discomfort caused by the tugging of the tube in the patient's throat when the lower esophagus was being distended, it was possible to keep an individual unaware of any alteration of the experimental situation.

EXPERIMENTAL RESULTS

The results of experimental distention of the lower esophagus, common duct, and upper small intestine are presented in tabular form for each patient, along with a short history of each case. In each table the characteristics of the clinical pain are presented first. Following this the results of experimental stimulation

are presented with the viscus stimulated indicated in the left-hand column, the location of pain in the middle column and in the sketch, and the quality of the sensation elicited indicated in the right-hand column

Experiment 1 CASE 1 L B (M G H No 520066) A 57 year old housewife entered the hospital on February 22, 1946, with colicky right midabdominal pain and icterus of 1 week's duration. Past history was essentially noncontributory. Physical examination was negative except for mild icterus and midabdominal tenderness, maximal on the right side. Laboratory studies revealed

Van den Bergh 1 2/1 9 milligrams per cent, prothrombin time 28 seconds (normal 19-22), Graham test showed a functioning gall bladder which was full of stones

Cholecystectomy and choledochostomy were performed on March 15, 1946. Stones were found to be present in both the gall bladder and the common duct although the latter was normal in size. The ampulla of Vater was dilated to a diameter of 4 millimeters. A T tube was inserted into the common duct. Cholangiograms made at the time of operation and on the tenth postoperative day showed a patent ampulla and no stones

Diagnosis cholelithiasis and choledocholithiasis

The patient remained asymptomatic throughout a 15 month postoperative period. Pain studies were performed on March 29, 1946 and are shown in Figure 1 and Table I

Experiment 2 CASE 2 A LaS (M G H No 516436) A 44 year old housewife entered the hospital on April 9, 1946, with intermittent sharp epigastric pain, of 15 years' duration, without jaundice or food intolerance

Physical examination was negative except for a right lower quadrant appendectomy scar. There was no abdominal tenderness. Laboratory examination was negative except for Graham test which showed a nonfunctioning gall bladder

Cholecystectomy and choledochostomy were performed on April 15, 1946. Three small stones were found to be impacted in the ampulla of the gall bladder and in the cystic duct, but none were found in the common duct. The ampulla of Vater was dilated to a diameter of 5 millimeters. A T tube was inserted into the common duct

Diagnosis cholelithiasis

The patient was asymptomatic throughout an 8 month postoperative period. Pain studies were performed on April 28, 1946 and are shown in Figure 2 and Table II

Experiment 3 CASE 3 M H (M G H No 118739) A 42 year old housewife entered the hospital on April 13, 1946, with midepigastric pain of 24 hours' duration which began one-half hour after eating an egg. A similar attack had occurred 5 months previously. There was a definite history of fat intolerance but not of jaundice. Physical exami-

nation revealed moderate right epigastric tenderness and spasm. Laboratory findings van den Bergh, 0 9/1 2 milligram per cent, serum amylase, 44 units (normal up to 35 units)

Cholecystectomy and choledochostomy were performed on April 14, 1946. An edematous pancreas was found and two stones were impacted in the cystic duct. The common duct was twice normal size but without stones. The ampulla was dilated up to a diameter of 8 millimeters. A T tube was inserted into the common duct

Diagnosis cholelithiasis and mild pancreatitis

The patient was asymptomatic throughout a 14 month postoperative period after which she had some epigastric distress. Pain studies were performed on April 26, 1946 and are shown in Figure 3 and Table III

Experiment 4 CASE 4 M R (M G H No 466120) A 43 year old widow entered the hospital on November 5, 1945, with intermittent, severe epigastric pain of 11 years' duration. During the last year preoperatively the pain radiated throughout the entire abdomen and to the back. She gave no history of jaundice or food intolerance. Physical examination revealed marked midepigastric tenderness. The Graham test showed good dye concentration and innumerable small stones in the gall bladder. White blood count, gastrointestinal roentgenogram, stool examination, and serum amylase were within normal limits

Cholecystectomy and choledochostomy were performed on November 24, 1945. The gall bladder was filled with small stones. The common duct and pancreas were normal. The ampulla was dilated up to a diameter of 5 millimeters and a whistle-tip catheter was inserted. On the tenth postoperative day a cholangiogram reproduced the patient's preoperative pain and showed no obstruction

Diagnosis cholelithiasis

The patient was asymptomatic until 8 months postoperatively when some food intolerance and headaches occurred. Pain studies were performed on December 5, 1945 and are shown in Figure 4 and Table IV

Experiment 5 CASE 5 S S (M G H No 519120) A 30 year old housewife entered the hospital on March 18, 1946, with a 2 months' history of intermittent, crampy, left epigastric pain associated with nausea and vomiting. There was no history of food intolerance, clay stools, or jaundice. Physical examination was negative except for generalized abdominal tenderness most marked in left upper quadrant, and rebound tenderness in left upper quadrant. Urinalysis, blood hemoglobin and cell counts, and gastrointestinal roentgenogram were within normal limits, van den Bergh 0 5/1 1 milligram per cent and 0 9/1 6 milligram per cent, serum amylase, 38 units and 34 units, prothrombin time, 25 seconds (normal 19-22). Two Graham tests gave "unsatisfactory visualization" of the gall bladder

Choledochostomy was done on March 25, 1946. The gall bladder was normal in appearance. The

Experimental pain		
a From common duct distention with fluid	Same as P including radiation	Same
b From common duct distention with balloon	Same as P including radiation	Same
c From pylorus and duodenum	Same as P with radiation to back but without radiation to lower quadrants	Same
d From lower esophagus	Same as P including all radiation	Same

Except for the duodenum or pylorus stimulation of all areas produced identical pain which was similar to the clinical pain. Duodenal or pyloric distention pain was different only in its lack of radiation to the lower quadrants.

common duct contained no stones but was found to be dilated. The pancreas was indurated with fat necrosis present near the ligament of Treitz. The ampulla was dilated to a diameter of 8 millimeters and a T tube was inserted into the common duct. Cholangiogram on the 14th postoperative day showed filling of Wirsung's duct with simultaneous reproduction of patient's "old pain", there was no obstruction to the flow of the dye into the duodenum. Diagnosis: chronic pancreatitis. It was decided to use prolonged choledochal drainage. The patient was asymptomatic until the T tube was accidentally removed 2 months later by the patient, after this time the "old pain" has recurred at irregular intervals. Pain studies were performed on April 23, 1946 and are shown in Figure 5 and Table V.

Experiment 6 CASE 6 KP (MGH No 507593) A 68 year old housewife entered the hospital on October 23, 1945, with intermittent upper midabdominal pain of 19 months' duration with occasional nausea, but no vomiting, food intolerance, jaundice, or acholic stools. The pain radiated to the lower abdomen and back when severe. Physical examination was negative except for a right mid-abdominal scar as a result of an old appendectomy, and slight generalized abdominal tenderness. Urinalysis, blood counts, hemoglobin, blood chemistry, prothrombin time, and gastrointestinal roentgenogram were essentially normal. Two Graham tests showed no dye in the region of the gall bladder. Pre-operative balloon distention of the esophagus, duodenum, and upper jejunum reproduced pain which was identical in location and character, and which

also was similar to the clinical pain which the patient suffered

Choledochostomy was performed on November 15, 1945. No gall bladder, cystic duct, or gall bladder fossa were found. The common duct was found to be dilated and contained multiple large stones which were removed. The ampulla of Vater was dilated. A T tube was inserted into the common duct. Cholangiogram was done on the 12th postoperative day and no evidence of obstruction was seen.

Diagnosis: Choledocholithiasis, agenesis of the gall bladder.

The patient was asymptomatic throughout an 18 month postoperative period. Pain studies were performed on November 28, 1945 and are shown in Figure 6 and Table VI.

Experiment 7 CASE 7 M W (MGH No 102749) A 78 year old veteran of the French Foreign Legion entered the hospital on May 2, 1946, with epigastric pain coming on after eating and present for 2 weeks, sometimes associated with chills and fever. Five months previously he had had a cholecystostomy following 1 week of similar pain. From then up to the present illness he had been discharging stones and bile intermittently from a persistent sinus tract in the right upper abdomen, but this tract had remained closed for the 10 days preceding readmission.

Physical examination revealed slight icterus, ankle edema, orthopnea, and slight right upper quadrant abdominal tenderness. There also was a right subcostal operative scar with a hernia and a subcutaneous stone. The white blood count was normal, serum amylase, 150 units, van den Bergh, 0.6/1.0 milligram per cent.

Cholecystectomy and choledochostomy were done on May 7, 1946. The gall bladder was shrunken, had fat necrosis on its surface and contained several small stones. The common duct was enlarged but contained no stones. The pancreas was swollen and edematous. The ampulla was dilated. A T tube and a ureteral catheter with balloon were inserted into the common duct. On the 12th postoperative day cholangiography reproduced the patient's preoperative pain but was otherwise negative.

Diagnosis: cholelithiasis, cholecystitis and pancreatitis.

Eight months following operation the patient had recurrence of high epigastric pain at which time a 1.5 centimeter gastric ulcer was demonstrated on the posterior aspect of the body of the stomach. His symptoms responded favorably to medical treatment, and the ulcer was no longer visible on gastrointestinal roentgenogram. His status at 16 months following operation is not known. Pain studies were performed on May 20, 1946 and are shown in Figure 7 and Table VII.

Experiment 8 CASE 8 A D'A (MGH No 20456) A 54 year old male entered the hospital on June 4, 1946, with recurrent left epigastric pain for which he had a subtotal gastric resection 7 years previously. Pathological report was "carcinoma in

situ." In addition a sterile abscess had been found in the head of the pancreas and a diagnosis of pancreatitis had been established. His pain continued intermittently until the present admission. No history of jaundice, clay-colored stools, or icterus could be elicited.

Physical examination was negative except for a left upper paramedian scar and slight tenderness in the left upper quadrant. Laboratory study revealed intermittent elevation of white blood count and van den Bergh. A gastrointestinal roentgenogram showed calcification of the pancreas but no other lesion. Several Graham tests were inconclusive. Serum amylase, blood lipase, and urine diastase were elevated.

Cholecystectomy and choledochostomy were performed on June 18, 1946. The gall bladder was normal. The common duct contained no stones, was 2.5 centimeters in diameter and had a constriction in its distal end. The pancreas was markedly indurated. A 3 millimeter diameter dilator was passed through the ampulla with difficulty and a T tube with an indwelling ureteral catheter balloon was left in the dilated portion of the common duct.

Diagnosis: chronic calcified pancreatitis.

Eight months after operation the patient continued to have pain until he underwent a left thoracolumbar sympathectomy on January 18, 1947. Following sympathectomy he has remained free of pain for 22 months. Pain studies were performed on July 14, 1946 prior to the sympathectomy and are shown in Figure 8 and Table VIII.

Experiment 9 CASE 9 M A (MGH No 256225) A 49 year old housewife entered the hospital on December 12, 1944, with intermittent epigastric pain, anorexia, nausea and vomiting of 15 years' duration. Twenty-six years previously, for this same complaint, she had had a cholecystostomy, then a cholecystectomy and choledochostomy without relief. Stones were said to have been found in the common duct. Because of the same symptoms since then she had had two more operations for pyloroplasty and choledochostomy without any abnormal condition being found in the common duct, and a T tube had been left in the common duct for 6 months without improvement.

Physical examination was negative, essentially, except for tenderness in the right epigastrium and several abdominal surgical scars. Serum examinations, blood chemistry, electrocardiogram, roentgenogram of spine, barium enema, gastrointestinal roentgenogram, and intravenous pyelogram were within normal limits except for a duodenal diverticulum and "fixation" of the duodenum.

Diagnosis: biliary dyskinesia.

Bilateral sympathectomy (D9 to D12 inclusive), with removal and resection of the great splanchnic nerves was performed on January 24, 1945. Nine months later the patient had had four mild attacks of left upper quadrant pain, although the previous right-sided pain had not recurred. Pain studies were performed on January 4, 1945 prior to sympathectomy and are shown in Figure 9 and Table IX.

Stimulation of all areas reproduced identical pain which was similar in type to the clinical pain.

SUMMARY OF RESULTS

A Comparison of pain experimentally induced from the lower esophagus, common duct and upper small intestine. As shown in the individual charts and as summarized in Table X it was found that there were certain similarities in the pain induced by distention of different viscera in the same patient in terms of location, radiation, quality, and intensity. It should be pointed out, however, that the amount of distention necessary to elicit pain of comparable intensity varied considerably from patient to patient.

Distention of the duodenum and of the upper jejunum produced an identical type of pain in all 5 patients so tested. By identical pain is meant discomfort which was indistinguishable as regards quality, location, intensity and radiation. Distention of the upper small intestine (duodenum or jejunum) and of the common bile duct produced identical pain in 7 out of 9 patients. In the 2 remaining patients the difference was one of radiation only. When distention of the lower esophagus was included in the comparison, the similarity of the pain was less striking. Five patients

TABLE X — COMPARISON OF PAIN EXPERIMENTALLY PRODUCED IN UPPER ABDOMINAL VISCERA

Viscera stimulated	Total cases	No of cases where pains were indistinguishable*	No of cases where pains were different
Esophagus upper small intestine and common duct	9	3	6
Esophagus and upper small intestine	9	3	6
Esophagus and common duct	9	5	4
Upper small intestine and common duct	9	7	2†
Duodenum and jejunum	5	5	0

*Indistinguishable as to quality location intensity, radiation
†Pain was the same except for a difference in radiation

felt that pain produced from the common duct and from the lower esophagus was indistinguishable, and 4 patients felt that the pain was different. Pain induced by lower esophageal distention was the same as that produced in the upper small intestine in 3 patients and was different in 6 patients. Thus it can be seen that pain from stimulation of all three areas was the same in 3 patients, while in the 6 other patients the pain was not comparable.

B Comparison of the patients' clinical pain with the experimentally induced pain. Pain in 6 patients was presumably due to disease of the biliary tract and in 2 patients it was apparently due to pancreatitis. One patient, Case 9, was having a recurrence of epigastric pain for which she states that she had a gall stone removed 26 years previously.

Seven patients felt that their clinical pain was reproducible both by distention of the common duct and by distention of the upper small intestine (Table XI). By reproducibility is meant pain which was similar as to quality, location, and radiation. In certain instances, possible damage to the structures did not warrant our attempting to induce pain of comparable intensity to the clinical pain. Two patients felt that pain from distention of the common duct and upper small intestine areas was the same as their clinical pain except for its radiation. In 4 of 9 patients distention of the lower end of the esophagus produced pain similar to the clinical pain. The chief difference in the esophageal distention

TABLE XI — REPRODUCTION OF CLINICAL PAIN OF BILIARY TRACT AND PANCREATIC ORIGIN BY MECHANICAL STIMULATION OF COMMON DUCT, DUODENUM, JEJUNUM, AND LOWER ESOPHAGUS

Viscera stimulated	Total cases	No of cases where experimental pain was same as clinical pain*	No of cases where experimental pain was different from clinical pain
Common duct	9	7	2†
Upper small intestine	9	7	2†
Esophagus	9	4	5

*Same in quality, location and radiation
†Pain was the same except for a difference in radiation

pain from the clinical pain noted in the 5 other patients was one of location, the discomfort from the balloon distention being located somewhat higher in the epigastrium than their own pain complaint.

Discussion. Data have been presented which compare the results of stimulating the common duct, upper small intestine, and esophagus in each of 9 patients who had had an exploration of the common duct. The discomfort from distention of these various viscera has also been compared to the clinical pain in these patients, in 7 of whom the pain was apparently due to a disturbance of the biliary tract and in 2, to pancreatitis. These studies have confirmed the results of Zollinger, McGowan and associates, of Layne and Bergh and others which have shown that epigastric and right upper quadrant pain with radiation to the back are produced by distention of the common duct (15, 16, 22). By distention of the common duct we were able to produce pain in the midepigastrium and in the right upper quadrant as well as discomfort radiating to the back. The fact that distention of the common duct could produce pain identical to that caused by distention of the duodenum or jejunum in a majority of our cases has not, so far as we are aware, been previously reported.

These studies have also shown that while distention of the lower end of the esophagus usually produces subxiphoid or high epigastric pain, as demonstrated by Jones (11), this procedure may in some patients give rise to pain lower in the epigastrium which is indistinguishable from the pain experienced from dis-

tention of the common duct or upper small intestine. It may be that this lower reference of pain from distention of the lower esophagus could be accounted for by the fact that our patients had organic disease.

We have also shown that our patients' clinical pain could be reproduced experimentally in all respects (in 7 of 9 patients) by distention of the common bile duct or of the upper small bowel and in some patients even by distention of the lower esophagus.

The striking degree of similarity between each of the 9 patients with respect to pain experienced from distention of the common duct and upper small intestine emphasizes how difficult it may be to distinguish on the basis of the pain reference or from the quality of the pain whether upper abdominal discomfort is arising from the biliary tract or from the upper small bowel. The fact that 2 patients with pancreatitis had their pain reproduced by stimulation of these structures emphasizes that this disease entity is likewise difficult to distinguish from disturbances of biliary and upper gastrointestinal tracts on the basis of the pain reference and quality of pain. It is worthy of note that the clinical pain, presumably from the biliary tract, in Case 1, was located in the right lower quadrant somewhat below the level of the umbilicus and that it was reproducible by balloon distention of the common duct and of the duodenum. This localization though atypical probably represents pain of biliary tract origin inasmuch as the patient has been asymptomatic for 15 months following cholecystectomy and inasmuch as the pain was reproducible by distention of the common duct.

A possible explanation for the similarity in the pain elicited from stimulation of the common duct and upper small intestine is that these structures as well as the pancreas have final common sensory pathways, namely, the visceral afferent fibers traveling in the great splanchnic nerves and over the lower thoracic sympathetic ganglia (14, 21). Smithwick and White, Craig, Archibald, Scrimger, and Grimson have all been able to abolish pain of the so called postcholecystectomy syndrome which is assumed to have its origin in the biliary tract by resection of the great splanchnic

nerves and of the lower thoracic ganglia (1, 8, 9, 17, 19). It has also been shown that section of these pathways likewise abolishes pain from balloon distention of the duodenum and upper jejunum (2). To what extent the great splanchnic nerves and the lower thoracic sympathetic ganglia conduct pain from the lower esophagus will be the subject of a subsequent communication.

It is appreciated that pain of visceral origin may be ill-defined and difficult of localization. However, the regularity with which each patient recognized the similarity of pains induced experimentally in different structures and their close resemblance to the clinical pain made us feel that the balloon distention procedure is a reliable method of investigating visceral pain mechanisms. Moreover, in certain instances the balloon procedure may help to clarify difficult diagnostic problems. Recently a patient came to our attention who complained of midepigastric pain which had recurred following a cholecystectomy. There was no clinical or laboratory evidence of common duct pathology. The only positive finding was a hiatus hernia. Balloon distention of the duodenum reproduced the exact location of the pain whereas distention of the cardiac end of the esophagus produced epigastric pain about 1 inch higher than the patient's complaint. At operation a stone was found and removed from the common duct. The relief of pain since operation is highly suggestive that the origin of the discomfort in this patient was from the common duct and not the hiatus hernia. The balloon distention procedure was felt to be helpful in identifying the origin of pain in this patient.

SUMMARY

1. A comparison of pain experimentally induced by distention of the lower esophagus, common bile duct, and upper small intestine has been made in each of 9 patients. The experimentally induced pain from these structures was also compared to the clinical pain in these patients, 7 having biliary tract disease and 2, pancreatitis.

2. Pain from distention of the common duct and upper small intestine was the same in 7 patients and different in 2 patients. When the

lower esophagus was included in the comparison, the similarity of pain was less striking, distention of all three viscera produced identical pain in only 3 patients

3 Distention of the common duct and upper small intestine reproduced the clinical pain in 7 of 9 patients, distention of the lower esophagus, in 3 of 9 patients

4 The striking similarity of pain induced from stimulation of (1) the common duct and upper small intestine and of (2) the experimentally induced pain to the pain of biliary tract disease and pancreatitis emphasizes how difficult it may be to distinguish between disturbances of these upper abdominal structures on the basis of the pain symptoms alone

5 It is suggested that the similarity of the pain from the viscera studied may be due to their having a common sensory supply, the great splanchnic and lower thoracic sympathetic nerves

THE LOCAL AND SYSTEMIC EFFECTS OF CHRONIC ULCERATIONS

LOUIS T BYARS, M D , F A C S , and GORDON S LETTERMAN, M D , St. Louis Missouri

THE care and management of acute, chronic, and recurrent skin ulcers constitute a surgical problem complicated by numerous physiologic and clinical variations. The successful therapeutic approach and well planned surgical procedure depend largely upon the understanding and attempted correction of these fundamental disturbances. Infection, general debilitation, hypoproteinemia, anemia, and chronic shock occur as complications. The most vigorous treatment, aimed at the prevention and correction of these factors, in many instances will retard rather than stop the patient's downward course. The only satisfactory final solution to the ulcer problem is the attainment of a well healed wound at the earliest possible moment (Table I).

Ulcers result commonly from burns, circulatory lesions, chronic bacterial infections, neurogenic disturbances, malignancies, and various forms of trauma. The wounds of a patient with full thickness loss of skin over a large area may react in one of the following ways (1) (1) The wound may show extreme epithelial activity in that there is a piling up of keratin at the margin without progress, or there is a hopelessly slow extension of the epithelial edge across the wound (Fig 1) (2) The wound may show no epithelial response whatever to the wound stimulus, and with the continual loss of body fluids and increasing debilitation, the outcome may be fatal (Fig 2) (3) The wound may heal completely only to break down repeatedly following insignificant trauma or limited activity of the patient. The constant wound stimulus of tension and inflammation sometimes causes excessive keratin formation. While this type of wound rarely becomes malignant, it may do so but at a late date (Fig 3) (4) Even small deep wounds, if allowed to remain in a dirty condi-

tion and if pain is permitted to go uncontrolled, may cause debilitation and marked disability may result. The loss of a small area of full thickness skin over a critical area, such as an eyelid or hand, may produce a serious deformity. The small unhealed ulcer resulting from circulatory disturbances or chronic infection, commonly seen on the lower extremity, may result in a major economic and physical handicap to the patient (Fig 4). Observation of many patients who have received dilatory treatment has emphasized the hopelessness of such management (Fig 5), an understanding of the systemic and local factors involved does much to further this realization.

LOCAL FACTORS IN WOUND HEALING

Loss of a partial thickness of skin should be followed by quick healing, since epithelial regeneration takes places from the deeper elements which persist. This type of healing must not be confused with the problem involved when a full thickness of skin has been lost. In such cases healing progresses by 2 processes. First there is an epithelial ingrowth from the remaining intact skin at the margins of the wound. Initial epithelization is rapid. However, progress is slowed as the epithelial border gets farther and farther from the margin of normal skin. The first regenerated epithelium may be of fair quality, but it becomes progressively poorer, eventually it is only a few cells in thickness, its base is not attached to derma, and none of the normal skin elements, such as hair follicles and sebaceous glands, are present. In the large wound epithelization often fails entirely after a time (Fig 5). Also, proceeding simultaneously with epithelial growth, granulation tissue is forming from the base of the wound and this tissue is converted into scar which contracts. The base of the wound is thus pulled together and is reduced in size so that the area which must be epithelized is thereby diminished.

From the Department of Surgery, Washington University School of Medicine, St. Louis, Missouri.

TABLE I—SUMMARY OF PERTINENT DATA ON PATIENT WITH BURN ULCER
SEEN AFTER 6 MONTHS OF DILATORY TREATMENT

Period	c.c. Administered			RBC	Hb		Patient's blood plasma		
	Blood	Plasma	Amigen		gm	%	Total protein gm %	Albumin gm. %	Globulin gm %
(a) Entry	(Am't prior to entry indefinite)			3 9	9 4	—61	5 8	2 7	3 1
(a b) Preceding popliteal grafts	2 500	1 250	0	3 1	8 4	—55	—	—	—
(b-c) Before skin grafting entire wound	3 500	0	40 000	3 56	9 7	—63	5 7	3 3	2 4
(d) One month after healed wound	0	0	0	4 86	14 3	—93	6 4	3 3	3 1

- (a) Upon entry two-thirds of the lower extremities (27% of the body surface) covered by filthy edematous granulations. Both legs in acute flexion.
 (b) First operation—popliteal adhesions severed, spaces grafted.
 (c) Second operation—granulating wounds completely covered with free split thickness skin grafts.
 (d) Only after a well healed wound had been obtained were the anemia, hypoproteinemia, chronic shock, etc., controlled.

Although this process may be life saving, it is also deforming especially in larger wounds or in wounds which involve critical areas, it causes the contracture, the ectropion of the eyelid, or the distortion of an extremity (Fig 6). Such a granulating wound is underlain with an inflammatory area. It is this attending inflammation which penetrates to the superficial joints, such as those of the finger, with the result that a partial or complete, and often permanent, ankylosis may follow even though the joint itself was not injured at the time of the tissue loss. If all factors are favorable, such a wound will heal, but if the area is large or subjected to trauma, oftentimes it will tend to break down. Under less favorable circumstances the wound will not heal, the epithelial ingrowth stops and the formation of scar tissue continues. The more dense the scar tissue and the greater its age, the less vascular it becomes. Thus, the chronic ulcer is soon surrounded by a cortex of dense, avascular scar which prevents further healing (Fig 5). An ulcer which at its onset may have been caused by varicosities, syphilis, or trauma, after a period of time can no longer be classified as a varicose ulcer, luetic ulcer, etc., but only as an ulcer per se (Figs 4 and 8). A varicose ulcer of this sort does not heal following apparently adequate control of varicosities. To continue to treat such an ulcer on the basis of its original etiology is to treat it for what it once was and not for what it is at the present time. Following the correction of circulatory or other persisting initial factors, the only adequate approach is excision of the

entire ulcer. The regenerated epithelium and underlying and surrounding scar must be removed down to tissue of adequate vascularity. This newly created wound should be covered with skin, preferably at the time of excision, in order to produce immediate healing of the area with tissue of good quality (Figs 3, 5).

LOCAL AND SYSTEMIC EFFECTS

Anemia. Three to 5 days after an acute burn, an anemia of severe degree may develop. This has been studied by Moore, who suggests that the following factors may participate in producing red cell loss: early hemolysis, increased cell fragility, blood destruction by unneutralized plasma antibodies, blood loss through an open wound, infection, metabolic disorders, and depressed bone marrow function, as well as the actual destruction of the blood contained in the burned tissues. From this point on until the wound is healed, anemia is a constant problem. Its production and continuation are tied up with all those factors producing general debilitation. All too often one is misled as to the patient's condition by reliance on laboratory determinations. The anemia of the chronically ill patient may be so masked by reduction in plasma volume that the red count, hemoglobin, and hematocrit fail to give an accurate measurement of real deficiency of hemoglobin and red blood cells.

Hypoproteinemia. Patients with at least 10 per cent of the body surface involved in third degree burns become serious nutritional problems because of the loss of nitrogen in the urine and from the denuded surface area (7). The

increased caloric requirements resulting from fever, infection and a higher metabolic rate further magnify the nutritional problem. Many workers have studied nitrogen balance and loss in patients with large ulcerative lesions. Particular attention has been focused on the burn ulcer. Taylor found as much as 45 grams of nitrogen excreted by 1 patient in a 24 hour period and directed attention to the inevitable result of the accumulated loss. Co Tui determined quantitatively the nitrogen loss in body exudates. He used slabs of fine pored cellulose sponges to collect the exudates. In a 24 hour period 1 patient exuded 0.42 milligram of nitrogen per square centimeter, while another exuded 2.26 milligrams of nitrogen per square centimeter from a denuded surface resulting from an avulsion. The significance of this loss is forcefully pointed out. If half of the body surface of a man weighing 70 kilograms and measuring 170 centimeters in height were to be involved in a burn, the 9,050 square centimeters so involved would lose per day according to one rate 23.75 grams of protein or the equivalent of 4,000 cubic centimeters of plasma or of 113 milligrams of meat, and according to the other rate 124 grams of protein or over 20,000 cubic centimeters of plasma or 600 grams of meat.

Ravdin suggested that "if the means to determine it were available, the first effect of protein undernutrition is a reduction in the amount of protein stored in the tissues of the body since every attempt is made to maintain the serum protein concentration at a nearly normal level." Localio has shown that there is actually a depletion of the fascial protein, while the serum protein concentration remains within normal limits. Subnormal serum protein determinations denote body protein deficiency, but the converse is not necessarily true. Multiple blood transfusions may bring blood proteins up to normal or near normal levels without restoring the body's protein reserves, giving a misleading idea as to the patient's condition. The excessive loss of nitrogenous products in the urine and from denuded surfaces and progressive regression in protein concentration indicate that the body protein stores are depleted in the patient with a chronic ulcer.

Fig 1 a, left Ulcer of 36 weeks' duration, patient having had 36 dressings under anesthesia during this period. Almost no epithelial growth has taken place. In addition to scar tissue contracture, there is shortening of hamstring tendons and sciatic nerve. b, Useful leg restored in small part of the time of previous disability. Correction obtained at 2 skin grafting operations, the first involving release of popliteal scar, application of split thickness skin grafts to the posterior surface of the leg and use of skeletal traction to overcome secondary contractures. At second operation anterior surface of leg was grafted.

Chronic shock This term has been provided by Clark, who presents a working concept of chronic shock. "A reduced total quantity of circulating blood in patients with nutritional deficiency was reported by Chang in 1932. Similar observations in hypoproteimemic animals have been recorded in the reports of the experiments of Holman, Mahoney and Whipple. In a study of patients with persistently unhealed war wounds attention was directed to a syndrome characterized by weight loss, reduced blood volume and increased interstitial fluid volume. All of these reports emphasize the coincidence of protein depletion and diminished blood volume. The surgically significant feature of reduced blood volume is an increased susceptibility of shock correctable by transfusion replacement of the blood volume deficit." It is on this basis that the syndrome has been designated as chronic shock.

Infection The chronic skin ulcer is always associated with contamination and with some degree of infection. So long as the contaminating bacteria are allowed to flourish, the ensuing infection will be a deterrent to wound

TABLE I—SUMMARY OF PERTINENT DATA ON PATIENT WITH BURN ULCER

All of these reports emphasize the coincidence of protein depletion and diminished blood volume. The surgically significant feature of reduced blood volume is an increased susceptibility of shock correctable by transfusion replacement of the blood volume deficit." It is on this basis that the syndrome has been designated as chronic shock.

Infection The chronic skin ulcer is always associated with contamination and with some degree of infection. So long as the contaminating bacteria are allowed to flourish, the ensuing infection will be a deterrent to wound

Fig 2 a, Huge granulating wound, nearly encircling trunk, as it appeared after being prepared for grafting by saline soaks, pressure dressings, and frequent mechanical cleansing. Patient debilitated and rapidly failing despite heroic supportive treatment. Pinch grafts applied to such a patient often do not prevent death because epithelization is too slow to check failure of vital processes. b, Intermediate result after covering approximately 50 per cent of open wounds with such split skin grafts as could be obtained from such an emaciated patient, plus homografts of split skin from 3 donors. Reduction of the wound by 50 per cent carried the patient over a critical period and initiated spontaneous epithelization. Homografts in this instance persisted up to $7\frac{1}{2}$ months, the longest survival in any of our cases. c, Complete healing without marked contractures finally obtained by further use of split skin grafts from patient's own body.

healing. Bacteria grow and multiply unless something is done to starve, remove, or annihilate them. Starvation may be accomplished by the mechanical removal of devitalized tissue. All serum exudate, necrotic tissue, and blood clots should be removed by gentle but thorough cleansing. Copious washing and irrigation of the wound will reduce the bacterial count. The changing of pus soaked dressings will mechanically remove masses of germ containing material. The frequent change of dressings and proper cleansing of the wound, rather than damaging the ingrowing epithelium, as is sometimes stated, aids its development through reducing tissue destruction by infection (Figs 2 and 3b).

Many agents have been advocated to control and destroy bacterial growth but none has been completely successful. All too frequently the substances used have proved more lethal

to viable cells than to bacteria. The control of such infections may be strengthened by the use of penicillin, streptomycin, and the sulfonamides and by bolstering the immune processes of the host, its eradication depends upon the careful surgical care of the local lesion. This implies the prevention of contamination, starvation of the bacteria by the removal of slough and secretion, and by the actual mechanical removal of the organisms which come with the proper application of surgical dressings, and the use of open drainage and wet dressings.

General debilitation. Marked weight loss and general debilitation have long been recognized as serious complications in patients with large chronic ulcerating wounds. This term simply serves to summarize the combined effect of infection, hypoproteinemia, anemia, pain, fever, inability to take and metabolize

Fig 3 a, Carcinoma developing in ulceration from burn repeatedly recurrent over a 53 year period b, Wound from cauterization of carcinoma properly prepared to receive split skin graft Note firm, compact, clean granulations resulting from pressure dressings and frequent cleansing Edematous granulations respond to such care and should never be destroyed with escharotic agents such as silver nitrate, which delays wound healing c, Healing by primary intention by application of split thickness skin grafts in 1 operation Patient eventually died of intra-abdominal metastases

Fig 4 a, An ulcer per se, initially caused by trauma The surrounding and underlying scar has prevented healing over a 3 year period b, Immediate healing obtained by deep and wide excision of the ulcer and application of thick split skin graft Has remained healed to date, 5 years, permitting normal use of the leg

adequate amounts of food, and loss of morale through pain and disability General debilitation can be prevented only by attaining a healed state From every standpoint a concerted effort should be made to obtain wound healing prior to this degree of debilitation (Fig 2)

TOPICAL APPLICATIONS TO SPEED WOUND HEALING

An understanding of the many problems involved leads one to believe that the search

for a magic drug which may be applied topically to eliminate scarring and speed healing will be of no avail In the past many agents have been acclaimed The wound characterized by part thickness loss of skin should heal either without scarring or with minimal scarring unless further loss of tissue is produced through the use of topical applications, improper dressings, or infection With the full thickness loss of skin, especially over large areas, healing must be by slower body processes Treatment which holds infection to a

Fig 5 a, left Ulcer caused by a burn 17 months previously, patient having been hospitalized at public expense for this period. Vertical scar edges indicate that spontaneous epithelization has ceased, although production of underlying scar is continuing, reducing the vascularity of the area. Poor quality of the spontaneously formed epithelium is apparent. b, Patient returned to productive activity 6 weeks after excision of ulcer and poor epithelium, relaxation of contracture by dissection, and application of split thickness skin graft.

minimum, supports the general condition of the patient, and does not injure tissue will result in the most rapid spontaneous healing

possible. No topical agent alone can achieve these results.

SURGICAL COVERING OF THE OPEN WOUND

Large areas of skin loss by avulsion may be replaced immediately (Fig 7). The more critical the area or organ involved, the greater the importance of immediate restoration of the skin surface. Emergency grafting of the fresh wound will prevent the deleterious local and systemic effects of chronic ulceration, deformity will be minimized and function will be restored at the earliest possible moment. In other types of tissue loss such immediate treatment may be impossible or not available. Nevertheless, the principle of rapid healing by means of skin grafts is just as applicable (5). Especially in the burned patient, the heroic procedures which were necessary to save the individual at the time of the acute burn must be continued, life saving measures must be carried on through the period when the medical and nursing staff may be tempted to relax because the crisis is over. A clean wound receptive to a skin graft should be quickly obtained. In from 3 to 5 weeks after injury large sheets of split thickness skin must be applied to the ulcerated area. Thus, the patient is restored to health in a matter of weeks rather than years. Pinch grafts are frequently used on such patients and may perhaps im-

Fig 6 a, left Distortion resulting from contracture of scar of spontaneously healed ulcer. b, Correction in 2 operations: (1) release of contracture by dissection and application of free full thickness skin graft, (2) interdigitation of local flaps across tight margins of grafts.

some instances be life saving by eventually healing the wound. With large areas, however, this type of graft simply alters the equation of the patient's tenacity of life versus slow wound healing, but does not solve the problem. The pinch graft does not give immediate healing. The procedure may be likened to the process of acquiring a lawn by planting seed versus sodding. Obviously, some patients present such large areas of ulceration that they themselves cannot supply enough skin for immediate coverage and therefore will rapidly lose ground. In many of them it appears that death is inevitable. It is in such individuals that the use of homografts, sheets of skin of split thickness taken from other individuals, may be life saving. Such skin has never been proved to persist except in the case of identical twins. However, it does convert a huge open wound with its many relentlessly destructive systemic effects into at least a temporarily healed area, with its many advantages. The use of such grafts is an emergency procedure to meet a crisis and in this respect may be likened to a blood transfusion where the donor's cells do not persist but do tide the recipient over a critical period of need. Such homografts in our experience "take" with the same readiness as the patient's own skin. Homografts have persisted with all the appearance of normal skin from 3 weeks to, in one instance, $7\frac{1}{2}$ months. The patient in each instance is thereby given a much needed reprieve (Fig 2). The maximum effort to produce healing in the critically burned patient must be made at the first operation (2).

Fig 7 a, above Avulsion of major portion of integument of forearm and hand presenting question of amputation, secondary repair with additional damage from inflammation attending delay, or immediate débridement and grafting b, Early result obtained by immediate grafting with small secondary graft to areas of further skin necrosis. Patient treated in conjunction with Dr. Oscar Hampton.

The small chronic ulcer. The leg ulcer constitutes a "sore spot" on any charity service or clinic. Such individuals rapidly lose their status as wage earners. Most surgical practices include a number of cases of such ulcerations which have proved intractable to the usual treatments. The most direct, quickest, and best approach to such problems is the adequate excision of the ulcer with its surrounding thin scar epithelium and underlying dense avascular scar. The defect is then covered immediately with a skin graft of intermediate thickness (3). Although such ulcers are often the result of faulty circulation

Fig 8 Diagram of the chronic ulcer, per se

in an extremity, after a period of time they persist either because of entirely local conditions or because of a combination of both general and local factors. Frequently, the general circulation of the extremity cannot be improved beyond a certain point. However, with the elimination of the local lesion, healing may often be maintained with limited use of the leg and the wearing of elastic bandages or supports. Long standing ulcerations resulting from osteomyelitis or compound fracture may likewise often be permanently eliminated (Fig 4)

SUMMARY

The basic principles in the management of chronic ulcerative skin lesions are discussed. Special emphasis is placed upon the local and systemic effects of such ulcers. Factors in wound healing and the local pathological status are outlined. Topical applications to speed wound healing are discounted. A permanently healed wound is the only satisfactory solution of the chronic ulcer problem, this may be obtained at the earliest possible

moment by the use of split thickness grafts

THE REGIONAL LYMPH NODE DISSECTION IN CANCER OF THE EXTREMITIES

JULIAN H. FRIEDEN, M.D., New York, New York

MALIGNANT neoplastic disease takes an annual toll of more than 180,000 persons in the United States. The mystery of malignancy is yet to be solved, but while research continues and is gaining momentum, radical surgical removal of the lesion appears to yield the best results for life expectancy. The extirpation of the regional lymph nodes in block dissection is a procedure designed to eradicate the first collection spot, where malignant cells lodge, after traversing the lymphatic vessels from the primary site. These procedures, the radical groin dissection and the radical axillary dissection, are frequently indicated in malignant lesions of the extremities and are to be used in conjunction with the radical local excision. Fifty-one of such dissections, done at the New York Post-Graduate Hospital, Tumor Division, for squamous cell carcinoma and malignant melanoma of the upper and lower extremities, were recently reviewed. Certain conclusions were reached:

THE LESION

Malignant neoplasms of the extremities may arise from any of the tissues present. They are the squamous cell carcinoma, the malignant melanoma (melanocarcinoma, melanosisarcoma), and the sarcomas (fibrosarcoma, myxosarcoma, liposarcoma, osteogenic sarcoma, leiomyosarcoma, rhabdosarcoma). The sarcomas were not studied in this series.

The squamous cell carcinoma. The epidermoid or squamous cell carcinoma of the extremities appears as ulcerated, encrusted, irregularly-shaped or round, raised masses usually with firm, indurated, rolled borders. The appearance depends greatly on the duration of the lesion and the predisposing factor or precancerous lesion namely, thermal or traumatic scars, senile keratoses, arsenical keratoses,

verrucae, irradiative, bacterial, and chemical dermatoses, osteomyelitic sinuses, and varicose and luetic ulcers. In 35 cases of squamous cell carcinoma studied, 8 patients or 23 per cent gave a history of a previous burn, 5 in old burn scars and 3 in scars of less than 1 year's duration. Two of the 35 patients had received intensive x-ray therapy, and 2, electrolysis for the removal of hair. The carcinoma arose in an area of lupus vulgaris in 2 cases, in an area of arsenical dermatitis in 2 cases, and in a birthmark in 1 case. Three had no predisposing factor other than an incident of trauma. No cause was mentioned in the other cases.

In general, this type is slow growing with a low grade of malignancy. The average age in this series was found to be 56 with the youngest at 30 and the oldest, 84 years. Seven or 44 per cent of 16 regional lymph node dissections showed metastatic lymph nodes. Taylor and Nathanson found the likelihood of metastasis increased with greater duration, larger size, and higher grades of malignancy. They found axillary metastasis in 36 per cent of 45 patients who had squamous cell carcinoma of the upper extremity for less than 1 year, and in 52 per cent of 45 cases of involvement of the lower extremity. DeBell and Stevenson thought that the duration of the lesion seemed not to influence the rate of metastasis but that the larger lesions, over 3 centimeters in diameter, had a greater tendency to metastasize than the smaller ones. In 6 cases studied in which regional lymph node metastasis and a fairly reliable history were present, the duration since onset varied from 8 to 36 months with an average of 19 months. Pack and Rekers report this time interval in the Memorial Hospital series of cases to be 30 months. Data in this regard are apt to be inaccurate because of the difficulty in ascertaining when the carcinoma began, especially when a precancerous lesion was present. In

From the Department of Surgery, New York Post Graduate Hospital, New York.

Fig 1. Squamous cell carcinoma of the hand of 4 months' duration. This lesion followed the burn described

the case of a 67 year old hat labeler, who sustained small burns on the dorsum of the hand by molten particles of gold, all the little burns healed but one, and at this site there grew a squamous cell carcinoma (Fig 1). Here, the history of 4 months could be considered accurate. Other inaccuracies regarding rate of metastasis may result from the failure to section and recognize the area of metastasis or the metastatic lymph node. It would be necessary for the pathologist to take thousands of serial sections of the block of tissue removed in order to avoid missing microscopic areas of metastasis.

Metastasis is common in squamous cell carcinoma of the extremities.

The malignant melanoma. This neoplasm and the squamous cell carcinoma have many characteristics in common but also differ greatly. The lesion often develops in a pigmented spot on the skin, grows as a mass, usually ulcerated, encrusted, pigmented, friable and indurated, raised, and rounded (Fig 2). It often appears as an innocuous little pigmented mass, irregular in shape, flat or slightly raised, and increasing slowly in size. Both sexes are equally affected, as are the young and the old. In 38 cases of malignant melanoma of the extremities, the average age was 46 years, the youngest being 18 and the oldest 69 years. DeCholnoky reported the malignant condition present in a child 15 months and 1, 5 years of age. The diagnosis in

children is apt to be made with difficulty because of the confusing microscopic picture. In 9 or 24 per cent of the 38 cases reviewed there was a history of trauma to a pigmented lesion previously present. The malignant melanoma, histologically appears carcinomatous or sarcomatous, and often both. It metastasizes freely by way of the lymphatic vessels and the blood stream. Metastatic lymph nodes were found in 23 or 66 per cent of the 35 lymph node dissections performed for malignant melanoma of the extremities. In these cases observed at this clinic the time interval since onset was $13\frac{1}{2}$ months. The shortest interval in this series was 3 months. Pack and Rekers in their series found this average interval to be 13 months. Again the inaccuracies previously cited regarding such statistical data would be present.

Metastasis is common in malignant melanoma of the extremities and may occur rapidly, especially in the larger lesions, which are easily irritated and traumatized, which increase in size rapidly, and which have been treated with various medications.

THE LYMPHATIC ROUTE

Lymph is derived from the interstitial fluids and enters a closed system of capillary loops which are composed of a single layer of endothelial cells. From groups of these loops, the reticula, emerge the finest lymphatic vessels which contain valves. As the vessels grow larger, they decrease in number, are provided with a smooth muscle layer, and are contractile. The lymph flows to the lymph nodes via these afferent vessels, which are more numerous than the efferent ones. In traversing the sinuses which partly surround the lymphocytic follicles of the lymph node, the flow is slowed. This slowing, together with the mechanical action of the meshwork of reticulum, renders the lymph node a highly efficient center of filtration, which removes emboli of malignant cells, bacteria, and foreign particles.

The rate of flow is increased by the increased formation of lymph and by the massage of the vessels. The smooth musculature in the larger vessels may aid the flow along with the pumping action of the diaphragm and the negative

pressure in the thorax and the negative pressure in the venous system at the jugular subclavian junction. The valves make certain of the forward motion of the flow. Thus exercise, massage, heat, motion, and bandaging an extremity will increase the drainage of lymph. An extremity which is quiet and dependent has an almost negligible lymphatic flow.

Lymph node metastasis is the result of an embolus of cancer cells which enters the lymphatic vessels and travels to the regional lymph node via the afferent lymphatic vessel. Occasionally, the metastasis is established by permeation, but most often by the embolic route. Once the malignant neoplasm is present in the lymph node, it may spread to other lymph nodes in the region by secondary embolism or by permeation, and when near veins, blood stream invasion may follow. Occasionally, blood stream emboli occur due to invasion of veins by the primary tumor.

Occlusion of the lymphatic vessels may reverse the direction of the flow of lymph which is normally proximal and centralward. This occlusion may be due to tumor emboli, to the blockage of lymph nodes by neoplastic tissue, to surgical removal, and to inflammatory processes. The stagnation of lymph results in distention of the lymphatic vessels and incompetency of the valves. Retrograde lymphatic neoplastic permeation may follow with edema of the extremity and the rapid appearance of metastatic nodules in the superficial lymphatics. This phenomenon has been evident in the malignant melanoma following regional lymph node dissection.

The lymph nodes of the axilla are in close relation to the chief veins of the axilla and receive afferent vessels which drain areas that coincide roughly with the distribution of these veins. The main lymphatic trunks of the arm are superficial, roughly parallel but anastomose freely on the flexor surface of the forearm. They tend to direct themselves medially toward the epitrochlear area and ascend on the medial aspect of the upper arm. A number of these trunks are interrupted by epitrochlear lymph nodes, commonly two or three lymph nodes superficially placed on the medial aspect of the arm above the internal epicondyle of the humerus. These nodes receive afferents chief-

Fig. 2 Malignant melanoma of the arm, a birthmark, which at the age of 38 began to increase in size. Here it is seen after 6 months of growth. Axillary dissection revealed metastatic lymph nodes.

ly from the ulnar aspect of the forearm and hand, but the anastomoses of these vessels are numerous. The efferents of the epitrochlear nodes as well as the other primary trunks pass to the lowest axillary vein group of lymph nodes. A few vessels go directly to the supraclavicular area while others go to higher groups in the axilla. Some of the trunks accompany the cephalic vein, and may be interrupted by intercalated lymph nodes in the deltoid pectoral groove or may pass to apical lymph nodes, or may go directly to the supraclavicular area. There are a few deep lymphatic vessels of the arm which accompany the deep blood vessels and are interrupted by inconsistent intercalated lymph nodes, the deep epitrochlear lymph nodes in relation to the brachial vessels, or the lymph nodes of the axilla.

The lymphatic vessels of the lower extremity are chiefly superficial and tend to follow the course of the veins. From the sole of the foot, the posterolateral aspect of the leg, and from the deep structures of the leg, the lymphatic vessels follow the short saphenous vein or the deep veins to reach the popliteal lymph nodes or pass directly to the deep femoral lymph nodes. From other parts of the leg and thigh, the lymphatic drainage passes to the superficial nodes of the long saphenous vein or directly to the deep femoral or external iliac lymph nodes. From the buttocks, the drain-

age accompanies the superficial circumflex iliac vessels to the groin and rarely to the hypogastric lymph nodes via the lymphatic trunks which accompany the gluteal vessels

THE OPERATION

The radical axillary dissection With the arm abducted to a right angle to the body, an incision is made on the anterior chest along the free border of the pectoralis major muscle. At the apex of the axilla, the incision is one-third of the distance from the free border of the muscle to the clavicle. It then curves and is continued down the arm to the point of the insertion of the pectoralis major. The skin flaps are widely dissected with only a minimum of subcutaneous fat remaining on the skin. The landmarks used to limit the extent of the dissection are the latissimus dorsi muscle posteriorly, the tendon of the pectoralis major muscle at the arm, the cephalic vein at the upper border, and the lateral border of the pectoralis major muscle which forms the anterior margin of the axilla. The skin is dissected to this line. The landmarks are exposed and the dissection is outlined. Progress is then made on the distal side of the cephalic vein with the sheath reflected mesially through nearly the whole length. The tendon of the pectoralis major is exposed and is transected so that there is enough stump remaining to allow resuture of the tendon later. The pectoralis minor is retracted. The muscle may be sacrificed if it appears to be involved in the pathologic process. The axillary fascia is then incised at the nearest possible point to the clavicle and the axillary vein is exposed. Working from the lateral to the vessel side, the thin fascia of the coracobrachialis and biceps muscles is removed and carried over the musculocutaneous nerve, median nerve, and brachial artery to the axillary vein without disturbing the fatty tissues around the nerves. The sheath of the axillary vein is incised. The vessels and nerves to the pectoralis major are ligated. The subscapular vessels, which enter the axillary vein from behind, are preserved. The dissection is carried over the brachial plexus. The subscapular space is cleaned out by blunt dissection, and the exposed long thoracic nerve of Bell is preserved. The speci-

men is then removed from the margin of the latissimus dorsi muscle mesially to the chest. The tendon of the pectoralis major is sutured to the tendinous insertion. A stab wound is made in the outer flap in front of the latissimus dorsi muscle to allow two small split rubber tube drains to be inserted to the summit of the axilla. The skin edges are approximated. All air and fluid is expressed, and a pressure type of dressing is applied. The dressing is usually not disturbed for 5 days. The drains are then removed and function of the arm is encouraged.

The epitrochlear lymph node dissection is occasionally performed along with the radical axillary dissection.

A longitudinal incision is made over the epitrochlear region, usually over palpable lymph nodes, from the middle of the arm downward to the region of the internal epicondyle. The skin flaps are widely raised. The biceps muscle is exposed in front and the triceps and flexor muscles of the forearm posteriorly. On the fascia of these muscles the dissection is then carried centrally toward the brachial vessels and nerves. The medial antebrachial cutaneous nerve and the basilic vein are divided as incisions are made in the fat. The brachial vessels and the median and ulnar nerves are exposed as the biceps and triceps muscles are retracted outwardly. The dissection is carried distally along these structures and the muscles until the antecubital or epicondylar region is reached. The fat is cut across and the basilic vein again ligated. The wound is closed and a firm dressing is applied to the elbow.

The radical groin dissection With the thigh on the involved side abducted and externally rotated with the knee slightly flexed over a sandbag, the incisions are made starting 2 inches above and 1 inch medial to the anterior superior iliac spine, sweeping downward in a wide ellipse to terminate in the mid thigh over Hunter's canal. The amount of skin removed varies with the amount of subcutaneous fatty tissue, the looseness of the skin, and the nodal involvement. With the skin divided, the margins of the wound are widely undercut and thus the skin flaps are carefully prepared. The thickness of subcutaneous fat remaining under the skin varies from 3 to 5 millimeters.

The subcutaneous fat is dissected to include the upper one-third of the anterior thigh, the inguinal region, and the lower abdominal wall over the iliac quadrant. The dissection is deepened to the underlying muscles to include the fascia with the fat in a block from above downward. The inguinal canal is exposed by incising the aponeurosis of the external oblique parallel to the inguinal ligament from the external to the internal inguinal rings. The adventitia of the femoral artery and vein is stripped. The great saphenous vein is ligated at the saphenous femoral junction and again where the dissected block overlies the middle segment of the sartorius muscle. The inguinal ligament may then be transected or allowed to remain intact and raised by dissecting it from the underlying attachment. The inguinal canal is further opened by incising the transversalis muscle down to the extraperitoneal areolar tissue. The fatty tissue about the iliac vessels, is swept downward and removed as part of the specimen. The node of Cloquet may be found anteriorly on the femoral vessels and is also included. Tissue overlying the obturator foramen is also included in the specimen. The deep epigastric vessels coming off at right angles from the external iliac artery and vein are ligated. The dissection is performed sharply. The inguinal canal is repaired as in a herniorrhaphy. It is possible to remove the entire specimen in one block which is theoretically better than dividing this potential neoplastic tissue into deep and superficial blocks. The dead space of Scarpa's triangle is obliterated by suturing the sartorius medially. The femoral vessels are thus protected. A spica type of dressing is applied by employing refined mechanic's waste in the groin and upper thigh for even pressure, with the thigh slightly flexed to lessen the tension on the wound and to permit the natural fold of the groin to form. This position is continued for 3 weeks. Any collections of serum are aspirated.

The popliteal lymph node dissection is rarely performed along with the radical groin dissection.

A vertical incision is made over the popliteal area. The skin flaps are prepared widely and a diamond-shaped area between the ham-

string muscles above and the two heads of the gastrocnemius muscle below is exposed as the dissection is deepened by two lateral incisions in the fat which converge and unite.

The floor of the dissection is formed by the fascia. The popliteal vessels and peroneal nerves are identified near the upper angle and are preserved. The short saphenous vein is ligated at the junction with the popliteal vein and as the dissection is carried distally, is again ligated at the lower angle of the operative field. After removal of this mass of tissue, the wound is closed and a pressure dressing is applied and the limb splinted. The pressure and splinting is maintained for 2 weeks.

COMPLICATIONS

There was no postoperative mortality in the 51 axillary and groin dissections studied. Pack and Rekers report 2 (1.6 per cent) postoperative deaths in a series of 122 groin dissections, 41 of which were bilateral. Taylor and Nathanson report 2 postoperative deaths or 3 per cent in 71 axillary dissections. They also report 10 or 5 per cent postoperative deaths in 199 cases of groin dissections, 5 of which deaths occurred in those who had bilateral groin dissections. The complications expected in any major surgical procedure are to be expected here, namely, pneumonia, atelectasis, cardiac failure, hemorrhage, thrombosis, and sepsis. Complications pertaining to the wound are fairly common. Eight or 16 per cent of the 51 patients in this series developed serious wound infections, slough and necrosis of wound edges with separation. There were several with minor delays in wound healing. The most frequent complication is edema of the extremity. Edema was present in varying degrees but fairly marked in 10 or 20 per cent. Five of these 10 patients had developed postoperative wound complications. Of these 10, the edema disappeared within 6 to 8 months in all but 1, who had fairly marked elephantiasis of the upper extremity following axillary and epitrochlear dissections. After 12 months there was marked improvement and the extremity was functionally good. Occasionally lymph and serum collect under the skin for long periods of time in large quantities.

TABLE I — FOLLOW-UP STUDY OF RADICAL AXILLARY AND GROIN DISSECTIONS

	Malignant melanoma	Squamous cell carcinoma
No patients	25	13
No with metastatic lymph nodes	15	4
No evidence of reappearance		
0-1 years	5	2
1-2	3	4
2-3	2	1
over 5	5 (20%)	5 (31%)
No evidence of reappearance with metastatic lymph nodes		
0-1 years	1	1
1-2	1	
over 5	3 (20%)	2 (50%)
Died of malignant lesion		
0-1 years	5	
1-2	4	1
2-3	1	

THE RESULTS

The follow-up has not been satisfactory (Table I). Thirty-eight or 74.5 per cent were examined periodically for varying lengths of time. The results obtained must be surveyed with certain reservations. There were differences in operative technique. Some of the dissections were not as radically performed as others. Histopathologic techniques vary also and certainly metastases have been missed by overlooking a lymph node too small to be recognized or by failure to section the involved portion of the lymph node.

Thus, 3 of the 15 patients who had dissections which showed metastatic malignant melanoma have no evidence of reappearance after 5 years. Two of 4 cases showing metastatic squamous cell carcinoma were free of positive signs after 5 years. Of those who died of the malignant lesion, all showed metastatic lymph nodes.

In the local excision of 35 squamous cell carcinomas, 4 or 11 per cent reappeared locally. In 38 malignant melanomas of the extremities, there were no local reappearances, but in 6 cases there were reappearances near the original excision or between the site of the original lesion and the regional lymph nodes which, in these cases, had been removed.

Nathanson and Taylor report 2 year cures in 12 or 29 per cent of 52 regional lymph node dissections for squamous cell carcinoma of the extremities which showed metastatic lymph nodes. They also report 7 of 40 positive dissections for malignant melanoma of the extremities free of reappearances for 5 years. DeCholnoky reports 3 of 16 positive dissections for malignant melanoma who have 5 year cures.

MANAGEMENT

A tumor of the extremities which is gradually increasing in size is to be handled with suspicion of neoplastic malignancy.

The most certain method of arriving at a diagnosis is the biopsy. If the lesion presents characteristics of a malignancy, then the frozen histopathological section may be performed, followed promptly by radical local excision if positive. In the case of the melanoma, no biopsy should be taken unless one is prepared to continue immediately with a radical excision. The excision of the malignant melanoma is to include a wide area around the tumor of normal-appearing tissue, subcutaneous fat, and an even larger area of underlying fascia with more removed on the drainage side. It is frequently necessary that the resulting defect be filled with a flap or with a skin graft, usually the split thickness dermatome graft. It is unnecessary to excise as radically with the squamous cell carcinoma. Usually, excision of the tumor with normal-appearing skin and subcutaneous fat is sufficient.

With the diagnosis of malignant melanoma of a toe or finger confirmed, amputation of that part of the extremity is indicated. With lesions of the extremities, an attempt should be made to excise the lesion but also to make certain of offering the patient a functional limb. The radical groin or radical axillary dissection should be performed in every case of malignant melanoma of the extremities. The local excision and dissection of the regional lymph nodes in continuity at the time of the initial operation offers more likelihood of arrest, when the primary site is so situated as to offer the advantages of a continuity procedure.

With the squamous cell carcinoma of the extremities, the dissection of the regional lymph nodes is advised regardless of the duration and appearance of the lesion, of the degree of malignancy, and of the state of the regional lymph nodes.

The lymph node dissection is postponed approximately 2 weeks after the local excision or after the local wound is healed and there has been active motion in the extremity. Any malignant emboli en route would then have the opportunity to reach the regional lymph nodes.

The epitrochlear and popliteal dissections are to be performed along with the axillary or groin dissection when highly suspicious lymph nodes are found in the region and when lymphatic drainage is expected to occur to these regions because of the particular location of the primary site. There would be a greater tendency to perform these dissections with the malignant melanoma than with the squamous cell carcinoma.

The follow-up of these patients is considered most important. The extremity must be carefully observed for reappearance locally, in the regional lymph nodes or anywhere in the limb. Suspicious lesions must be removed as they appear. These patients should be seen monthly during the first postoperative year. The follow-up should continue as long as the patient lives.

The complication, edema of the extremity, which is probably the result of lymphatic blockage and vasospasm, is handled by rest, elevation, and elastic bandaging. If the edema persists, the sympathectomy or stellate ganglion blocks, or intravenous procaine may be of value in relieving the vasospastic element.

RATIONALE

Surgically, the regional lymph nodes are accessible. The malignant lesion when accessible is to be eradicated. There can be no certainty that emboli of the primary lesion have not arrived at the regional lymph nodes. It has been shown that palpation of a lymph node is not to be considered reliable in diagnosing metastasis. Regional lymph nodes were not palpable in 12 of the 30 dissections in which metastatic nodes were present. The

Fig. 3 Photomicrograph of section of axillary lymph node which contains metastatic malignant melanoma cells, as indicated with arrows.

axillary and inguinal nodes are often enlarged, the result of a previous inflammatory process in the extremity.

A 37 year old white female presented herself to the Tumor Clinic with a lesion which had been present on her finger for about 1 year. There was a bluish discoloration and slight ulceration. Biopsy revealed malignant melanoma and an amputation of the finger was performed, and 3 weeks later an axillary dissection was done. No nodes had been palpable previously. Review of the sections revealed one section to contain a few isolated pigmented metastatic cells free in the sinuses of the lymph nodes (Fig. 3). The embolic theory is supported. There is no evidence of reappearance after 6 months.

It may be said that many of the dissections were performed and no metastatic nodes were found. A few of these negative dissections were probably positive but there is another value even though metastases were not found. The squamous cell carcinoma and the malignant melanoma disseminate most often by

the lymphatics. The interruption and removal of the main drainage trunks and collection areas provide a block to further dissemination. Other emboli may occur especially following the operative procedure, but the emboli will be trapped in the extremity and may appear to be surgically eradicated unless a collateral vessel is traversed. Lymphatic vessels regenerate slowly.

Occasionally an embolic shower as previously described occurs following local removal and regional lymph node dissection for malignant melanoma, when many malignant metastatic skin nodules appear between the site of local excision and the regional dissection. When such an incident occurs, prompt amputation or disarticulation might be indicated.

The procedures are not difficult to perform. The complications encountered are few in number and are not serious in nature.

CONCLUSION

Fifty-one radical axillary and groin dissections were performed for squamous cell carcinoma and malignant melanoma of the extremities.

Metastasis is found to be common to the regional lymph nodes via the lymphatic route. Regional lymph node dissections are usually indicated and are to follow the radical local excision of the primary lesion.

Careful, frequent follow-up observation is essential.

TRANSTHORACIC NEPHRECTOMY (RIGHT) FOR TUBERCULOSIS OF THE KIDNEY

VINCENT J O'CONOR, M D , F A C S , and JEROME R HEAD, M D , F A C S ,
Chicago, Illinois

SURGEONS primarily interested in thoracic and upper abdominal surgery have been approaching lesions of the esophagus and stomach through the left diaphragm with increasing frequency during the past few years. This thoracicoabdominal approach has in the main been no more hazardous to the patient than a simple abdominal one and has offered much facility in anatomical exposure. Those who have been especially concerned with surgical procedures on the kidneys and adrenals have been traditionally fearful of injuring the diaphragm or of entering the pleural cavity.

The continuing advance in the technique of thoracic surgery was put to a most rigid test in the treatment of thoracic and upper abdominal wounds in the recent war. The records of these surgical accomplishments, which have not yet been completed, testify to the fact that the diaphragm can no longer be considered as a barrier to anatomical approach to the structures lying directly beneath it.

In discussing "The Thoraco-Abdominal Casualty," Wylie, Hoffman, Williams and Rose have recorded a series of 903 patients in whom thoracic and abdominal wounds were dealt with through a transdiaphragmatic approach. A portion of their excellent report will be of interest to urological surgeons. Transdiaphragmatic procedures in which thoracotomy alone was employed and the kidney was injured were tabulated in Table I.

These authors point out that through the transdiaphragmatic approach on the right side, the field of exploration of the abdomen was limited to the superior surface of the liver, the right kidney, and the hepatic flexure of the colon.

On the left side, the problem is somewhat different, the absence of the liver mass, and

the relationship of the fundus and body of the stomach, spleen, splenic flexure of colon, body and tail of pancreas, and the left kidney to the anterior surface of the diaphragm, not only makes for easy accessibility to these organs through the diaphragm, but also permits greater facility of exploration and suture from below. The exposure which gave the best approach to transdiaphragmatic work was the posterolateral one, in the region of the ninth and tenth ribs.

Marshall, in his discussion on this subject, states that exposure of the left kidney is made easy through an enlarged incision in wounds of complicated thoracorenal-abdominal injury and that these patients tolerate nephrectomy, or repair of kidney, extremely well by the transdiaphragmatic approach.

Fox, in a review of 270 cases of thoracicoabdominal wounds, reported the removal of an injured right kidney through a transdiaphragmatic approach in 2 patients. These were primary emergency operations done in a forward hospital and later treated at a General Hospital. Both patients recovered.

Harper has called attention to the great advantages experienced in the removal of a tumor of the *left* adrenal gland by a transdiaphragmatic retroperitoneal approach. In response to a personal query, Harper stated that he had not known of a similar case ap-

Fig 2 The kidneys overshadowed the right diaphragm and lungs June 16, 1948

proached through the right diaphragm and wondered if the body of the liver would interfere with a free retroperitoneal exposure of the adrenal and kidney

The authors, being confronted with the necessity of attempting to remove the right kidney by transthoracic approach, made a careful survey of the literature and could find no recorded instance of a planned *right* transthoracic nephrectomy except in the cases of emergency war surgery already cited

Huggins, of Chicago, Mortensen, of Melbourne, Australia, and Chute, of Boston, have all reported on the advantages of left transthoracic nephrectomy in massive tumors of the kidney. Chute, in reporting to the 1948 meeting of the American Association of Genito-Urinary Surgeons, stressed the great advantage conferred by the wide exposure afforded by this route when dealing with large left renal tumors. He described three such operations and was of the opinion that, in addition to facilitating the removal of the kidney, the exposure permitted dissection under vision of malignant nodes about the

kidney pedicle. Since the medial aspect of the wound was prolonged past the end of the diaphragm and into the abdomen, Chute prefers to describe his procedure as "thoracoabdominal" instead of "transthoracic." Chute, Mortensen, and Huggins have purposely made no attempt to keep the procedure retroperitoneal in their operations through the left diaphragm.

The following case report is unique, both in the unusual anatomical condition occasioned by the patient's deformity and in the surgical procedure utilized to remove the right kidney.

Olga P., housewife, age 36 years, was referred by Dr. S. Abrahams on June 21, 1946. She complained of marked urgency and frequency of urination with pain over the suprapubic region. The frequency had been gradually increasing for the past 2 months. At that time she voided every 30 minutes day and night, although at times she would have nocturia only one to two times. The past history was that of a tuberculous infection of the spine beginning at the age of 2 years. This condition had left her with a marked kyphosis but her general health had been satisfactory until the onset of her urinary symptoms. Aside from the marked deformity occasioned by the kyphosis the patient's general condition was negative on

Fig 3 Marked deformity of spine is present in dorsal region

Fig 4 Superior calyx of right kidney narrowed, middle and lower calyces appear normal

examination, and the heart and lungs were normal to ordinary physical examination. The blood pressure was 150/110. The abdomen could not be palpated because the thoracic cage was so displaced that the lower ribs lay below both iliac crests. The breathing, therefore, seemed to be mostly abdominal. There was some suprapubic tenderness. All reflexes were normal. The blood count showed 4,470,000 red cells, 91 per cent hemoglobin, 10,700 white cells, normal differential. The urea nitrogen was 18.3 milligrams per cent. The urine on numerous examinations showed large numbers of leucocytes and clumps of pus. The catheterized specimen of the urine showed no growth on ordinary culture media after 48 hours. Acid fast bacilli were present on direct smear of the bladder urine.

Cystoscopic examination, under pentothal anesthesia, showed that the bladder capacity was contracted to 90 cubic centimeters. Both ureteral orifices were rather wide and gaping, but not typically 'golf hole' in appearance. Definite tubercles were seen in the region of the trigone and in scattered areas of the bladder wall. Both ureters were readily catheterized 30 centimeters with No. 6 French catheters. Cloudy urine was obtained from the right and clear urine from the left. After the injection of phenolsulfonephthalein there was a prompt appearance of the dye in 3 minutes from the left and a marked delay in appearance from the right. After 20 minutes the dye was heavily concentrated from the left and about a two plus output from the right. Urine

Fig 5 Retrograde pyelogram showed marked destruction of superior pole of right kidney

Figs 6 and 7 Specimen of right kidney

was taken from the bladder and both kidneys for acid-fast stain and guinea pig inoculation. X ray examination was carried out with considerable difficulty because of the marked deformity of the spine (Fig 1). The kidneys overshadowed the right diaphragm and lungs (Fig 2). A marked deformity of the spine is present in the dorsal region as a result of an old tuberculous process (Fig 3). There is no shadow suggestive of stone in the kidneys, ureters, or bladder. Retrograde pyelograms showed normal pelvic and ureteral outline on the left side. The right pyelogram showed a narrowing of the superior calyx with a moth-eaten appearance of the major superior calyx. The middle and lower calyces on the right appeared normal in outline. There is a suggestion of a narrowing of the upper end of the ureter at the junction of the renal pelvis (Fig 4). The patient was afebrile during her stay in the hospital. The guinea pig inoculation from the bladder and right kidney was positive for acid-fast bacilli. No acid fast bacilli were found from the left kidney and repeated smears from the left kidney were negative. Due to the unusual anatomical situation in this patient further observation was advised.

The patient returned to the hospital on December 1, 1946, stating that the urgency and frequency were less bothersome than on previous admission. She had been resting at home and had gained 25 pounds. The physical findings at this time were essentially the same except that cystoscopy revealed a more active tuberculous involvement of the bladder than previously found. At this time there was some question as to whether there was a tuberculous infection of the left kidney although the pyelograms revealed normal outlines and several smears of the urine were negative for acid-fast bacilli. Repeated injections of guinea pigs with urine from the left kidney showed no acid fast bacilli. Surgical approach to the right kidney seemed out of the ques-

tion at this time and she was advised to have streptomycin therapy. She received 50 grams of streptomycin, 1 gram daily for 50 successive days. This was followed by immediate improvement in the frequency and the patient was able to go as long as 1½ to 2 hours without voiding.

The patient was not again seen until June 14, 1948, at which time she re-entered the hospital complaining of a marked remission of urinary frequency, burning, and suprapubic pain. Physical findings at this time were essentially the same except the patient had gained weight and aside from her urinary symptoms seemed to be enjoying excellent health. Cystoscopic examination at this time revealed inflammatory lesions scattered throughout the floor and lateral walls of the bladder but no evidence of tubercle formation as previously had been seen at cystoscopy. Both ureters were catheterized and the urine from the right was turbid, urine from the left crystal clear. After the intravenous injection of phenolsulfonephthalein only a small amount of dye was obtained from the right kidney in a 30 minute period. The dye from the left concentrated normally and appeared in 3 minutes. Retrograde pyelogram on the right (Fig 5) showed marked destruction of the superior pole of the right kidney with apparent erosion of the middle and superior calyces. After careful study of the patient it was decided that an attempt should be made to remove the right kidney through a transthoracic approach. The patient was placed on streptomycin, 1 gram daily, for 1 week prior to operation. The operation was done June 22, 1948.

In this patient, as the result of extreme kyphosis, the thoracic cage dropped down over the pelvis so that there was no space posteriorly for a classical kidney incision.

and no space anteriorly for an abdominal approach. Study of the pyelogram showed that the right kidney lay at the level of the tenth rib posteriorly. Accordingly, this was chosen as the site for the approach. Intratracheal ether and oxygen anesthesia was administered and the patient was placed on her left side. Through an incision extending laterally from the spine, over and in the direction of the tenth rib, a long segment of the rib was resected outward from the transverse process. Incision through the rib bed led into a free pleural cavity just above the reflection of the diaphragm onto the thoracic wall. To permit a wider separation of the ribs, the eleventh rib was transected posteriorly. The diaphragm was then incised parallel to its insertion into the chest wall. This led into the retroperitoneal space and into the perirenal fat. The kidney could be easily palpated and was located directly beneath the incision. The rib spreader was inserted and the ribs spread to secure a wider exposure. The general pleural cavity was packed off with laparotomy pads. The incision through the diaphragm was well below the lower posterior border of the liver and at no time during the operation did the liver come into view.

The kidney, together with all attached perirenal fat, was readily freed and careful visual separation of adhesions and several enlarged lymph nodes was most satisfactorily accomplished under direct vision. The renal pedicle was first tied, without clamping, with No. 2 chromic catgut. A pedicle clamp was applied and the pedicle was severed. The ureter was freed as far down as possible and was divided between clamps. After removal of the kidney the ureteral stump was transfixed and ligated with No. 1 chromic and the cut end was cauterized with phenol and alcohol. The exposure permitted a rapid and easy procedure.

The incision in the diaphragm was closed with a continuous suture of No. 1 chromic catgut. A mushroom catheter was inserted into the pleural cavity through a stab wound above the incision. The rib bed was closed with a continuous suture of No. 1 chromic catgut and the muscles, fascia, and skin with interrupted silk sutures. Following the operation the drainage catheter was attached to a water

Figs. 8 and 9. Front and profile views of patient, September 30, 1948.

trap to permit the escape of fluid and air. A roentgenogram taken the day following the operation showed that the lung had completely expanded and that there was no fluid or air in the pleural cavity. The drainage catheter was removed the following day.

Pathology report. Right kidney (Figs. 6 and 7). The gross specimen preserved in formalin consists of a kidney and numerous irregularly shaped pieces of fibroadipose tissue. The kidney weighs 95 grams and measures 7.5 by 4.5 centimeters. The capsule is thickened and strips with difficulty exposing a nodular gray and tan granular surface. The kidney is moderately decreased in consistency and resistance to section. The cut surfaces reveal the cortical and medullary markings to be indistinct. The parenchyma has been replaced for the most part by necrotic cysts which have a rough gray wall and are filled with pale yellow material. In other places the tissue is yellow and firm. The fibroadipose tissue is gray and yellow and is not remarkable in appearance, consistency, and resistance to section. Within the adipose tissue is a blood vessel which has a lumen almost occluded by yellow firm tissue.

Microscopic section of the kidney reveals the usual architecture to be distorted. The glomeruli for the most part have degenerated into fibrotic tufts. The capsules of Bowman are moderately to markedly thickened. The arterioles and arterial arteries reveal marked arterio-sclerosis with minimal thickening, hyalinization, and cholesterol deposition. The parenchyma is markedly infiltrated with lymphocytes and plasma cells. Moderate hyperemia is present. The parenchyma is compressed. The remaining area is occupied by areas of necrosis surrounded by loose connective tissue. There is marked lymphoid infiltration about the periphery of these lesions and an occasional giant cell. Section of the ureter reveals the muscular wall to be thin and markedly infiltrated with lymphoid cells, frequent neutrophils, and eosinophils. The mucosa is absent and flanked by loose connective tissue in which the cellular infiltration is moderate. The central portion of the wall consists of necrotic tissue. The fibroadipose tissue adjacent to the ureter shows slight focal hemorrhage, but otherwise the structure appears as usual. Sections from the distal part of the ureter which is included with the specimen show the wall to contain many lymphocytes and large mononuclear cells. In the lumen there is necrotic material. Sections of the kidney stained by the Ziehl-Neelsen technique show no acid fast bacilli.

Diagnosis. Tuberculous poly nephritis, tuberculous ureteritis.

The patient's convalescence was completely uneventful. The temperature rose to 101 degrees with a pulse of 100, 48 hours after operation. During the following 3 days the temperature gradually returned to normal and the pulse stabilized at 80. From the fifth postoperative day on there was no elevation of temperature. The wound healed per primam and the stitches were removed on the eighth day. The patient was discharged on the seventeenth postoperative day. She had been up and about after the third postoperative day. Her urinary symptoms improved spectacularly from the day of operation onward and when the patient left the hospital she was

voiding every 3 hours and without pain as against painful frequent urination every 30 minutes before operation. One gram of streptomycin daily was continued during the 17 postoperative days. This patient has continued to enjoy improved health and when last seen on June 1, 1949, the urine was sparkling clear and contained no pus and was negative for acid-fast bacilli. The bladder capacity was 220 cubic centimeters and the nocturia had decreased to one or two times

SUMMARY

A right transthoracic nephrectomy is reported. A tuberculous kidney was removed in a patient with such an extreme kyphosis that access to the kidney through a lumbar or abdominal incision was impossible. The exposure obtained was even more satisfactory than that usually developed through an ideal lumbar incision. The position of the liver offered no interference and the operation was entirely retroperitoneal. Convalescence was as rapid and smooth as in patients who have had the conventional operation.

So far as we can ascertain, this is the first recorded *planned* operative procedure for removal of the *right* kidney by the transthoracic route.

THE USE OF FREE PERITONEAL GRAFTS IN INTESTINAL ANASTOMOSES

SPENCER T CHESTER, M D , H GLENN BELL, M D , F A C S , and
H J McCORKLE, M D , F A C S , San Francisco, California

RECENTLY Devine reported a method for the prevention of leakage in intestinal anastomoses. In a group of dogs, the colon was divided and anastomosed with a single, continuous, through-and-through silk suture which transversed all layers of the intestine. This obviously inadequate method invariably resulted in fatal peritonitis in the control animals. In another group of dogs, the anastomoses were covered with grafts of free peritoneum which were fixed to the intestine with plasma-thrombin clots. The grafts were held in position with pressure applied for 5 minutes, no sutures were used. All grafts remained adherent and only 1 of the animals died of peritonitis, this being one in which a perforation was made in the graft at operation. The grafts were firmly fixed in 24 hours, and after 4 days, the margins could not be lifted. Devine also placed a free peritoneal graft around an exteriorized loop of human intestine and obtained similar results.

Further information about the use of free peritoneal grafts to cover intestinal anastomoses was sought in the following experiments.

Sixteen dogs were anesthetized with sodium pentobarbital and the abdomen opened through a low vertical abdominal incision. A rectangular graft of peritoneum 1 by 3 inches in size (which included some or all of the thin fascia of the posterior rectus sheath) was removed from the lateral aspect of the laparotomy incision (Fig 1). A loop of colon was divided and a closed end-to-end anastomosis performed with a layer of single interrupted No 40 cotton sutures (Fig 2). The free

peritoneal graft was placed around the anastomosis, peritoneal side down, after the graft had been moistened with thrombin solution (500 units per cubic centimeter of physiological saline) and the intestine at the site of anastomosis was moistened with serum. The graft was then sutured in position with interrupted sutures of No 100 cotton (Fig 3). Bubbles of air were removed from beneath the graft. The laparotomy incision was closed with interrupted sutures.

There were no deaths, and no evidence of peritonitis in the 16 experiments. In these experiments the grafts probably did not contribute significantly to the prevention of peritonitis as there was no mortality or evidence of peritonitis in a group of 8 similarly anastomosed, but ungrafted control animals.

The grafts of 11 of the animals were examined 3, 5, 7, 9, 12 and 14 days postoperatively, and those in the remaining 5 animals were seen 44 to 120 days postoperatively. The grafts remained completely viable in every animal and the outer raw surface was covered with epithelium as early as the twelfth postoperative day. Adhesions around the graft were observed in 10 of the 11 dogs which were examined in the first 14 days, and in most of these 90 to 100 per cent of the graft was covered with omentum, small intestine, or with mesentery.

In the 5 animals whose grafts were seen in 44 to 120 days postoperatively, 2 had adhesions, and in these cases they covered approximately 40 per cent of the surface of the grafts. These grafts were firmly adherent to the intestine and appeared to be covered with endothelium. There was no evidence of stricture at the site of anastomosis or of dilatation or hypertrophy of the intestine proximal to the anastomosis in any of the animals. There was some tendency for the grafts to contract transversely after being in place several weeks,

Fig 1 A, Removal of peritoneal graft from lateral edge of laparotomy wound B, Peritoneal graft after removal from the abdominal wall

but this was not evident in the first 2 post-operative weeks

Microscopic examination of the grafted intestine removed 3 days postoperatively showed the graft to be thick, edematous, and infiltrated with an acute inflammatory exudate which consisted mainly of polymorphonuclear neutrophil cells. The space between the graft and the intestine was filled with acute inflammatory exudate. There was no evidence of vascularization or fibroblastic infiltration. The serosa and subserosa of the colon showed marked vascular congestion. Microscopic examination of the grafted area removed on the fifth postoperative day revealed vascularization of the edematous graft due to the ingrowth of capillaries. At this time fibroblasts were present and the acute inflammatory exudate had disappeared. The space between the graft and intestine was filled with early granulation tissue containing many dilated capillaries and fibroblasts. The acute inflammatory exudate had disappeared except in areas immediately surrounding the cotton sutures. The serosa and subserosa of the intestine showed vascular congestion and capillaries and fibroblasts projected from this re-

gion into the space between the graft and the intestine. At 7 days the granulation tissue between the graft and intestine showed more evidence of organization and the capillaries and the fibroblasts tended to run perpendicularly from the intestine to the graft, and the beginning of collagen formation was seen. At 9 days the graft was still vascular and thickened and showed collagen deposition, and vascularization and fibroblastic proliferation were less evident. At 14 days the graft was still thick but the granulation tissue was much less evident. The collagen deposition was unchanged. The outer surface of the graft was covered with endothelium. The area between the graft and intestine was not distinguishable from graft or intestinal wall.

The specimens removed 44 to 115 days postoperatively showed the grafted area still thickened but otherwise indistinguishable from the normal serosa and subserosa of the intestine, and sutures were surrounded by fibrous tissue.

In these experiments, a serum-thrombin solution was used instead of a plasma-thrombin clot. This was not intentional but was due to an oversight at the onset of the experiment. However, because the results were satisfactory, the serum-thrombin solution was used for the entire series. This serum-thrombin mixture does not clot, nor does it have any immediate adhesive properties of note, it is slightly "sticky" to touch, but this is not sufficient to hold a graft in place without sutures. Thus, these experiments demonstrate the part free graft alone plays in sealing off the anastomosis site. It is well known that the opposing serosal surfaces of the peritoneum are the important structures sealing off a gastrointestinal anastomosis and that this sealing process takes place within 12 hours after the anastomosis. It appears reasonable to expect a peritoneal graft to behave similarly, especially if it is held against the intestinal wall with the slight tension produced by suturing it in position. It is conceded that these grafts might have taken just as well without the use of the serum-thrombin mixture. However, it appears preferable to seal free peritoneal grafts by the plasma-thrombin clot method because of the immediate sealing and

Fig 2

Fig 2 A, Site of division of colon B, One layer closed end-to-end anastomosis, interrupted No 40 cotton sutures were used

Fig 3 A, Placing of graft around site of anastomosis B, Free peritoneal graft sutured in position around site of anastomosis

Fig 3

fixing effect and also because of the possible value of the use of the serum thrombin mixture in the early nutrition of the free peritoneal graft

Another point for consideration is the fact that the peritoneal side of the graft was placed next to the anastomosis leaving the raw surface facing the peritoneal cavity. The reason for doing this has been indicated in the preceding paragraph. Also it was the method used by Devine. The main objection to this procedure is the fact that adhesions form on the exposed unperitonealized surface. They were found in 90 per cent of animals in the first 2 weeks and in 40 per cent after 6 weeks. Experiments to study a similar procedure in which the raw surface of the graft is placed next to the intestine against the anastomosis

are being carried out at the present time in the laboratory

The use of sutures in place of pressure to hold the grafts in place appears preferable as sutures diminish the tendency for the graft to slip

SUMMARY

Free peritoneal grafts were applied to anastomoses of the colon in 16 experimental animals. Gross and microscopic studies indicated that the grafts remained completely viable and adherent. Such grafts caused no constriction at the site of intestinal anastomoses.

THE EFFECT OF INTRAMEDULLARY NAILING ON THE HEALING OF FRACTURES

An Experimental Study

WILLIAM T FITTS, Jr, M D, BROOKE ROBERTS, M D, STANLEY I SPOONT, M D,
and VERN W RITTER, M D, Philadelphia, Pennsylvania

SURGEONS have long sought a safe method of treating fractures that would effect complete immobilization of the bone fragments, allow complete mobilization of the rest of the body, and yet not retard bone healing. Intramedullary nailing, introduced by Kuentscher (2, 3, 4) of Germany in 1940, has been advocated as approaching this goal. Although the method was used extensively by European surgeons during World War II, it has only recently begun to attract much attention in the United States (5, 7).

Considerable dispute has arisen over the efficacy of nailing, and many surgeons have emphasized the risk of complications from its use, notably shock during operation, and post-operative infection. Another controversial but fundamental issue is the effect of the nail on fracture healing. Kuentscher (3) himself stated unequivocally that the nail stimulates callus formation and speeds the healing process, which has been disputed by other investigators (1, 6). After extensive work with intramedullary nailing, Boehler concluded that the nail often inhibits callus formation and said, "This finding constitutes the greatest disappointment that I have experienced as a physician, because I had set the highest hopes upon the callus stimulating effects of the medullary nail."

So far as we have been able to determine, these opinions have been based either on clinical impressions or on uncontrolled experiments. Because it is probable that intra-

medullary nailing is the best method now available for the treatment of certain types of fractures and that its use will become more widespread, it seemed desirable to obtain more exact information concerning its effect on fracture healing. This we have attempted by a study of experimental fractures of the dog's ulna.

METHOD

When a dog's ulna is fractured in the distal half, the fragments do not become significantly displaced or angulated due to the immobilizing effect of the intact radius and interosseous membrane. The fragments eventually unite in good position without any other form of immobilization and without restriction of the dog's activity. Such a fracture is excellent for testing the effect of variables on healing.

In our experiments the ulna was exposed bilaterally under aseptic precautions in dogs anesthetized with intravenous nembutal (25.0 mgm per kilogram). The ulnas were fractured transversely with a one strand Gigli saw at corresponding levels, usually at the junction of the middle and distal thirds. On one side a stainless steel Kirschner wire (diameter 1.2 mm) was inserted through the olecranon process into the medullary cavity and past the fracture site into the distal fragment. The wire usually filled the marrow cavity in the vicinity of the fracture. The opposite side was similarly drilled, but the wire was then removed, making the presence of the wire the only variable (Fig 1). Because each dog served as its own control, all systemic factors which might alter fracture healing—e.g., age, sex, nutrition, activity,—were eliminated. As a prophylactic measure against infection 300,000 units of penicillin in oil were injected intramuscularly at completion of operation.

Fig 3 Steinmann pin inserted through the knee into medullary cavity of the dog's femur a, Roentgenogram taken immediately after operation b, Four weeks after fracture Periosteal callus noted opposite the two points where pin contacts inner cortex c, Eight weeks after fracture.

mm) were used (Fig 3) On the control sides the bones were drilled in a similar manner, but the pins were then removed In 1 dog the radius was fractured in its distal half while in the opposite leg the ulna was fractured and a Kirschner wire inserted through the olecranon (Fig 4)

RESULTS

In every instance extensive periosteal callus at a distance from the fracture site was noted on the pinned side That the reaction was not due to infection was indicated by freedom from clinical signs of infection and absence of infection when the dogs were later sacrificed Boehler has attributed some types of periosteal callus ("periosteal appositions") to rusting of the nail In these experiments no instance of rusting of wire occurred The periosteal reaction reached its peak roentgenologically at about 4 to 6 weeks after pinning and then gradually disappeared The reaction was most striking in dog No 7 (Figs 5 and 6)

We believe that an explanation for this callus is furnished by the experiments in which

Steinmann pins were inserted into unfractured femurs The periosteal reaction was found only opposite the points where the pin was in direct contact with the inner side of the cortex (Fig 3)

The results were generally consistent in the 8 dogs whose ulnas were fractured and a single Kirschner wire inserted on one side (Table I) In 1 instance the bone was fractured in the proximal third, and nonunion occurred on both sides In the remaining 7 dogs callus at the fracture site appeared earlier on the pinned side in every instance Two dogs died of distemper before union occurred In 4 of the remaining 5, union occurred more rapidly on the pinned side (Fig 7) In only 1 instance did union occur earlier on the unpinned side The average time for union on the pinned side was 4 months and on the unpinned side 6 months Although callus at the fracture site appeared sooner on the pinned side and although union was quicker on the pinned side, the maximum callus at the fracture site seen on the roentgenograms was usually greater on the unpinned side

Fig 1 Dog's ulna fractured bilaterally at similar levels with a Gigli saw. Roentgenograms taken immediately after operation. a, Left leg, Kirschner wire inserted through the olecranon process and past the fracture site. b, Right leg medullary cavity drilled but wire removed.

A fracture of the type described is a severe test of healing. It is transverse, it is in a location where union is commonly slow, and the fragments are distracted for a distance equal to the width of the Gigli saw since the intact radius maintains the length of the leg. The distraction is readily apparent on all the roentgenograms. It is not surprising, therefore, that union was uniformly slow on both sides. The slow rate of healing tended to magnify minor differences on the two sides and thus make the method especially appropriate for experimental purposes.

The degree of immobilization was not exactly similar on the two sides. It was evident at operation that the wire gave more rigid

Fig 2 Dog's ulna fractured bilaterally at junction of middle and distal thirds. Roentgenograms were taken immediately after operation. a, Control side which was not drilled. b, Kirschner wire has been inserted into each fragment.

fixation of the fragments. However, rotary motion, which is thought to be one of the commonest causes of nonunion of the distal ulna in man (8), was retained on the pinned side because the wire was not flanged.

EXPERIMENTAL DATA

Fourteen mongrel dogs were operated on. In 8 dogs the operation was performed exactly as described above. In 3 dogs the Kirschner wire was divided at the fracture site in order to eliminate the factor of better immobilization by the wire and its effect on bone healing (Fig 2). In 2 dogs large pins were inserted into unfractured long bones of the hind leg. Stainless steel Steinmann pins (diameter 4.0

Fig 6 Same dog as Figure 5 Roentgenograms taken 5 months after fracture Good union on both sides The periosteal callus has nearly disappeared

*1 fracture in proximal ulna

Fig 8 Photomicrograph of a longitudinal section through fracture site of pinned ulna of Dog No 1 8 months after fracture and immediately after removal of wire Note good bony union and absence of marrow elements No significant reaction to the wire is seen

Fig 4 Bilateral foreleg fractures with a Gigli saw. Roentgenograms taken immediately after operation. a, Right leg radius fractured just distal to middle. Note that the ulna does not prevent shortening. b, Left leg ulna fractured and Kirschner wire inserted. Note that the stronger radius prevents shortening and maintains distraction.

In 3 dogs the Kirschner wire was cut at the fracture site in order to eliminate the factor of immobilization by the wire. One dog died from pneumonia $2\frac{1}{2}$ weeks after operation but of the 2 which survived both had more rapid union on the unpinned side (Fig 9).

At autopsy no difference could be noted at the fracture site between the pinned and the unpinned sides of the dogs whose ulnas united. Infection was not found by gross examination in any instance. Microscopic examination showed only minimal signs of reaction to the wire (Fig 8).

Results were most interesting in the dog whose radius was fractured (Fig 4). When

Fig 5 Dog's ulna fractured bilaterally with a Gigli saw. Roentgenograms taken 4 weeks after fracture. a, Control side. b, Pinned side showing extensive periosteal callus involving almost the entire shaft.

this dog bore weight, the intact ulna, not being strong enough to support the weight of the dog, broke at the level of the radial fracture. The effect of distraction on the rate of healing was then strikingly demonstrated. Figure 10 shows the abundant callus seen at 3 weeks in this leg. Union took place in 6 weeks without any form of immobilization and with both bones broken (Fig 11) whereas the opposite ulna distracted by the intact radius united only after 36 weeks.

COMMENT

The fact that callus appeared more rapidly and union took place more quickly on the

pinned side in the first group of experiments suggested that the presence of the wire stimulated healing. Yet when the wire was divided at the fracture site, the pinned side healed less rapidly. In this case it was noted at operation that immobilization was better on the unpinned side. This was due to the fact that the insertion of the pins from the fracture site required temporary displacement of the fragments and consequent damage to the interosseous membrane. It appears that in each instance the factor determining more rapid union is the degree of immobilization and not the presence or absence of the wire per se. Periosteal callus formation at a distance from the fracture was definitely associated with the presence of the intramedullary wire. The mere destruction of the marrow cavity by the insertion of a wire, which was then removed, did not produce a periosteal reaction, nor was periosteal reaction caused by rusting of the wire.

In the third group of experiments, when a pin was inserted into the unfractured femur, periosteal callus appeared only opposite the points where the pin contacted the inner side of the cortex. This strongly suggests that the periosteal callus is produced by a pressure phenomenon. Such an explanation fits in well with the fact that in our experiments the periosteal reaction subsided concomitantly with the loosening of the wire and release of the pressure stimulus.

SUMMARY AND CONCLUSIONS

1 The insertion of an intramedullary wire into the dog's ulna fractured experimentally

produces periosteal callus over an area often far removed from the fracture site. This callus reaches its maximum on the roentgenogram at 4 to 6 weeks and is gradually absorbed. It appears to have little effect on the healing of the fracture and is not the result of destruction of the marrow. We postulate that this callus is caused by pressure of the wire on the inner cortex and that its disappearance is due to absorption of bone and the release of pressure.

2 Fractures of the distal half of the ulna heal more rapidly if a wire is inserted through the medullary cavity past the fracture. The more rapid union is probably due to the better immobilization which is effected by the wire and not to any callus stimulating effect of its presence.

3 It is probable that the presence of an inert foreign body in the medullary cavity does not significantly delay or speed fracture healing.

4 The deleterious effect on fracture healing produced by distraction is strikingly shown by these experiments.

Fig 1 Periodic acid Schiff's reagent (PAS) technique applied to normal cervical epithelium. The basement membrane is seen to stain heavily. The basal cells contain no glycogen. Large amounts of heavily staining glycogen are seen in the more superficial cells.

Fig 2 Case 2. On the left, PAS reaction applied to intraepithelial carcinoma at its point of junction with normal epithelium. The short oblique line of Schiller is well demonstrated. On the right, PAS reaction applied after digestion with malt diastase. This identifies the heavily staining intracellular granules seen in the left hand picture as glycogen.

carcinoma of the cervix earlier and thereby improve therapeutic results, the diagnosis being made without invasion. It is not by any means clear that carcinoma in situ is actually carcinoma. For this reason the present series of cases of carcinoma in situ and allied lesions of the cervix have been studied histologically and histochemically. The histochemical study allows another approach to a subject that has been well worked previously. We believe that it does add some information and may assist in the interpretation of several types of lesions of the cervix uteri.

MATERIALS AND METHODS

The material included in this report comprises the cervical biopsies and surgical specimens from the charity service of the Jefferson-Hillman Hospital during the period July 1, 1947 to August 1, 1948. During this time there were 2,697 biopsies and surgical specimens of all types. Eight cases had been definitely diagnosed as carcinoma in situ and showed the typical intraepithelial changes. The original slides were reviewed, additional sections cut and stained by the period acid (PAS) Schiff's method. It was found that glycogen could be demonstrated by PAS after formalin fixation and autotechnicon handling.

Six patients were colored and 2 were white. The average age was 35 years. Two women were pregnant, 1 was an intrauterine preg-

nancy, the other a tubal pregnancy. An outline of these 8 cases is presented in Table I.

Three typical cases are reported in some detail.

CASE REPORTS

CASE 1. C. R., a 37 year old colored female was admitted with the chief complaint of a heavy feeling in the abdomen associated with a mild low abdominal pain. Menstrual history was negative except for prolonged bleeding (2 weeks) during her last menstrual period. Physical examination revealed an irregular firm mass filling the lower abdomen and extending up to 3 fingerbreadths below the umbilicus. On pelvic examination this mass was thought to be continuous with the uterus. Laboratory work revealed a red blood cell count of 3,000,000 with a hemoglobin of 10.5 grams. White blood cell count and differential were essentially normal as was the urinalysis. The Kahn was reported positive. The clinical impression was multiple fibromyomas of the uterus, and after one 500 cubic centimeters whole blood transfusion a total hysterectomy was performed without difficulty. Postoperative course was entirely uneventful.

Routine section of the cervix showed an almost complete loss of the normal stratification in the stratified squamous epithelium. The cells had the same appearance from the basement membrane out to the most superficial cells. For the most part they were round and somewhat hyperchromatic. Occasional very large nuclei could be found and a few multilobed nuclei were noted. Mitotic figures were noted occasionally. A few polymorphonuclear leucocytes were seen scattered between the epithelial cells. In an additional section a segment of seemingly normal stratified squamous epithelium was noted. At one point there was a rather abrupt transition to epithelium that was definitely hyperactive. The cells here showed no stratification. The nuclei were hyperchromatic, they showed considerable variation in size and shape and sometimes tended to line up in spindle cell formation (Fig. 3).

HISTOCHEMICAL STUDIES ON GLYCOGEN IN CARCINOMA IN SITU OF THE CERVIX UTERI

J F A McMANUS, M D, and LYMAN FINDLEY, M D, Birmingham, Alabama

A DESCRIPTION of the staining of glycogen in paraffin sections of carcinoma in situ and other lesions of the cervix uteri is presented in this paper. It includes a brief discussion of carcinoma in situ based upon the morphological and chemical features of the lesion.

Normal cervical squamous epithelium contains a large amount of glycogen. This is best shown (Fig 1) in section with the periodic acid Schiff's reagent (PAS) method (2,3) by which glycogen and the basement membrane of the epithelium color purple. The identity of the intraepithelial granules as glycogen can be proved by digestion with malt-diastase by the method of Lillie and Greco (Fig 2). Glycogen is lacking in carcinoma of the cervix (5).

Carcinoma in situ of the cervix uteri denotes atypical epithelial cell masses which are still within the basement membrane although otherwise resembling carcinoma. The term is used synonymously with intraepithelial carcinoma, preinvasive carcinoma, and Bowen's disease of the cervix. The concept of carcinoma, recognizable without invasion, dates from Schiller's report of 1933 in which he describes the advancing margin of florid carcinoma of the cervix as sometimes having points of junction with the normal squamous epithelium. These points of junction show the atypical carcinomatous cells retained within the basement membrane and not actually invading.

A series of 19 cases are reported by Schiller in which atypical areas, corresponding to the advancing margin of carcinoma, are seen in otherwise normal cervixes and are taken to be early carcinoma (6). In none was there clinical evidence of cancer. Eight patients of the 19, or 42 per cent, are less than 40 years of age. Points of junction between normal and abnormal epithelium resemble those seen in frank carcinoma.

The concept of Schiller is then that cancer of the cervix may be preceded by a noninvasive stage. Meyer has studied the matter and suggests some doubt that the preinvasive stage always progresses to definite cancer. TeLinde and Galvin believe that there may be a lapse of quite some time, perhaps years, before frank cancer develops from such lesions. They have studied and described a series of early carcinoma cases in some detail.

TeLinde and Galvin describe hyperactivity beginning in the basal layer of the cervical epithelium, then progressing more superficially to involve the entire thickness of the epithelium (7). This produces a disturbance in the architecture of the epithelium so that normal stratification is lost. The cells become more numerous and they show variation in size, shape, and staining quality, much like invasive cancer cells. At this stage the lesion is Schiller's early carcinoma, or carcinoma in situ. It is thought that the entire thickness of the epithelium is taken over by the hyperactive basal cells before invasion begins. Cervical glands are described as a favorite route of the beginning invasion.

Types of junction between normal and hyperactive epithelium are described by TeLinde and Galvin. The hyperactive and normal epithelium may be demarcated by a short oblique line of Schiller. In other cases a long oblique line can be made out demarcating the hyperactive basal layers below from the normal upper epithelium.

These authors report 11 cases of extremely early carcinoma in which the average age of the patient is 36 years as compared with the average age of 48 years for carcinoma of the cervix in general. It is believed that this indicates the possibility of a surface lesion existing for years before the development of invasion.

The whole emphasis on intraepithelial carcinoma is based upon attempts to recognize

Fig 1 Periodic acid Schiff's reagent (PAS) technique applied to normal cervical epithelium. The basement membrane is seen to stain heavily. The basal cells contain no glycogen. Large amounts of heavily staining glycogen are seen in the more superficial cells.

carcinoma of the cervix earlier and thereby improve therapeutic results, the diagnosis being made without invasion. It is not by any means clear that carcinoma in situ is actually carcinoma. For this reason the present series of cases of carcinoma in situ and allied lesions of the cervix have been studied histologically and histochemically. The histochemical study allows another approach to a subject that has been well worked previously. We believe that it does add some information and may assist in the interpretation of several types of lesions of the cervix uteri.

MATERIALS AND METHODS

The material included in this report comprises the cervical biopsies and surgical specimens from the charity service of the Jefferson-Hillman Hospital during the period July 1, 1947 to August 1, 1948. During this time there were 2,697 biopsies and surgical specimens of all types. Eight cases had been definitely diagnosed as carcinoma in situ and showed the typical intraepithelial changes. The original slides were reviewed, additional sections cut and stained by the periodic acid (PAS) Schiff's method. It was found that glycogen could be demonstrated by PAS after formalin fixation and autotechnicon handling.

Six patients were colored and 2 were white. The average age was 35 years. Two women were pregnant. 1 was an intrauterine preg-

Fig 2 Case 2. On the left, PAS reaction applied to intraepithelial carcinoma at its point of junction with normal epithelium. The short oblique line of Schiller is well demonstrated. On the right, PAS reaction applied after digestion with malt diastase. This identifies the heavily staining intracellular granules seen in the left hand picture as glycogen.

nancy, the other a tubal pregnancy. An outline of these 8 cases is presented in Table I.

Three typical cases are reported in some detail.

CASE REPORTS

CASE 1. C R, a 37 year old colored female was admitted with the chief complaint of a heavy feeling in the abdomen associated with a mild low abdominal pain. Menstrual history was negative except for prolonged bleeding (2 weeks) during her last menstrual period. Physical examination revealed an irregular firm mass filling the lower abdomen and extending up to 3 fingerbreadths below the umbilicus. On pelvic examination this mass was thought to be continuous with the uterus. Laboratory work revealed a red blood cell count of 3,900,000 with a hemoglobin of 10.5 grams. White blood cell count and differential were essentially normal as was the urinalysis. The Kahn was reported positive. The clinical impression was multiple fibromyomas of the uterus, and after one 500 cubic centimeters whole blood transfusion a total hysterectomy was performed without difficulty. Postoperative course was entirely uneventful.

Routine section of the cervix showed an almost complete loss of the normal stratification in the stratified squamous epithelium. The cells had the same appearance from the basement membrane out to the most superficial cells. For the most part they were round and somewhat hyperchromatic. Occasional very large nuclei could be found and a few multilobed nuclei were noted. Mitotic figures were noted occasionally. A few polymorphonuclear leucocytes were seen scattered between the epithelial cells. In an additional section a segment of seemingly normal stratified squamous epithelium was noted. At one point there was a rather abrupt transition to epithelium that was definitely hyperactive. The cells here showed no stratification. The nuclei were hyperchromatic, they showed considerable variation in size and shape and sometimes tended to line up in spindle cell formation (Fig. 3).

TABLE I

Case No	Patient	Age years	Date	Presurgical biopsy	Surgical procedure	Date	Pathologic examination of surgical specimen
1	C R	37		None	Total hysterectomy	11 20-47	(1) Squamous cell carcinoma of cervix in situ (2) Fibromyomas of uterus intramural subserous and submucous (3) Endometrial polyp
2	M P	48	7 12 48	Carcinoma in situ	Total hysterectomy	7 19 48	(1) Carcinoma in situ of cervix (2) Subserous intramural and submucous fibromyomas of uterus (3) Chronic cystic cervicitis (4) Adhesions on peritoneal surface of uterus (5) Proliferative endometrium
3	C L	33	11 26 47	(1) Chronic cervicitis (2) Chronic cervicitis (see comment) (3) Carcinoma in situ of cervix chronic cervicitis	Total hysterectomy and right salpingo-oophorectomy	20-48	(1) Hyperplasia and atypicalities of growth in cervical epithelium* (2) Carcinoma in situ (previous biopsy) (3) Multiple intramural fibromyomas of uterus (4) Benign endometrial polyp (5) Hemorrhagic corpus luteal cyst (6) Healed chronic follicular salpingitis (7) Fibrous peritoneal tags and adhesions on uterus
4	L H	41	5 10-48	(1) Possible carcinoma of cervix (2) Squamous cell carcinoma in situ of cervix (3) Squamous cell carcinoma from vagina	Insertion of radium in to uterus, cervix and vagina (5760 mgm hours)	6 25 48	None
5	R O	35	11 10-47	(1) Squamous cell carcinoma of cervix**	Total hysterectomy bilateral salpingo-oophorectomy	12 1 47	(1) Squamous cell carcinoma of cervix in situ (2) Fibromyomas of uterus intramural subserous (3) Normal tubes and ovaries
6	Mrs V W	33	12 23 47 12 30-47	(1) Carcinoma in situ	Total hysterectomy right salpingectomy appendectomy	1 10-48	(1) History of biopsy showing carcinoma in situ (2) Right tubal pregnancy with hemorrhage (3) Chronic cervicitis (4) Proliferative endometrium
7	Mrs E F	23	6-10-47	(1) Chronic cervicitis metaplasia of endocervical glands single epithelial mass with atypical features (2) Possible squamous cell carcinoma of cervix (3) Severe chronic cervicitis marked squamous metaplasia with atypical areas	Total hysterectomy appendectomy	9-6-47	(1) Chronic cervicitis with probable carcinoma in situ
8	P S	30	6-4 47 6-9-47	(1) Probable carcinoma of cervix, small nabothian cyst (2) Probably squamous cell carcinoma (in situ) of cervix	Total hysterectomy	6-28 47	(1) Squamous cell carcinoma of cervix Grade I (hist.) (2) Uterus with 12 cm fetus

*See detailed report Case 3

**The surface epithelium in this biopsy showed a loss of stratification with considerable variation in nuclear size. Occasional mitotic figures were noted. There is invasion in the cervical glands, but nowhere can invasion beneath the basement membrane be discovered. Periodic acid stain reveals an absence of glycogen in all this hyperactive epithelium. Sections of the cervix after surgery shows essentially the same picture. We are of the opinion that this represents early carcinoma with beginning invasion.

PAS technique revealed a complete absence of glycogen in the hyperactive epithelium just described (Fig 4)

CASE 2 M P, a 45 year old colored female, sextigravida, quintipara, one abortion, admitted with the chief complaint of a mass in the abdomen. She had had profuse bleeding with her menstrual periods for the past 7 months. Physical examination revealed a firm nodular mass filling the lower abdomen and extending up to 2 fingerbreadths above the umbilicus. On pelvic examination this mass was thought to be continuous with the uterus. The cervix

was said to be clean. All laboratory work was essentially negative.

Biopsy of this cervix showed only a small portion of epithelium appearing normal. The remaining epithelium showed a complete loss of normal stratification. Large hyperchromatic cells resembling the basal cells filled the entire thickness of the epithelium. Mitotic figures were fairly numerous and polymorphonuclear leucocytes were noted between the epithelial cells. The transition between this hyperactive epithelium and the normal epithelium was noted to be rather abrupt.

Fig 3 Case 1 Hematoxylin and eosin stain. The carcinoma in situ is seen to the right, the normal epithelium on the left. Demarcation is by the short oblique line of Schiller.

Fig 4 Case 1 The PAS reaction has been applied to the field corresponding to Figure 3. The total absence of glycogen in the hyperactive area to the right is demonstrated.

A total hysterectomy was done and a large fibroid uterus removed without difficulty. The postoperative course was entirely uneventful. Microscopic examination of the cervix after hysterectomy showed the epithelium to be thickened in places. There were short blunt downgrowths but seemingly no extension past the basement membrane. The normal stratification was lost and the cells were markedly hyperchromatic. They varied considerably in size and shape, and mitotic figures were fairly numerous. In places the cells tended to line up in spindle cell formation. In one section large clumps of hyperactive epithelial cells were found deep in the fibrous tissue of the cervix. The picture here was identical with that described in the surface epithelium. In no place could extension beneath the basement membrane be found. PAS technique revealed a rather marked absence of glycogen in all the hyperactive epithelium.

CASE 3. C.L., a 33 year old colored female, primigravida, primipara, was seen in the out patient department with a complaint of low abdominal pain and backache which had been present for intervals for the past year. Physical examination was essentially negative except for a cervix that was enlarged two to three times and which appeared eroded. It was felt that the corpus of the uterus was pulled to the right and semifixed. There was a mass in the left adnexal region the size of a grapefruit. This patient had three cervical biopsies and was followed in the out patient department for a period of 3 months. During this time the adnexal mass gradually decreased in size until it was only about 4 centimeters in diameter.

The first biopsy showed a definite chronic cervicitis with large numbers of lymphocytes beneath the stratified squamous epithelium. The stratification of the epithelium was well preserved but an occasional large nuclear form was noted. PAS technique on this specimen showed glycogen to be present in the epi-

thelium but in somewhat smaller quantities than we usually see in normal cervical epithelium. The second biopsy 10 days later showed occasional areas in the epithelium in which the normal stratification of the epithelium was not present. The cells in these areas were relatively uniform but did tend to line up in spindle cell formation. Mitotic figures were rare. In areas where the plane of section was definitely perpendicular to the surface the epithelium seemed about normal. PAS technique applied to this epithelium showed large amounts of glycogen in the definitely normal areas. Glycogen was absent in the abnormal areas but this was thought to be due to the plane of section passing through basal cells. The third biopsy showed the stratified squamous epithelium markedly thickened with a loss of the normal stratification. Large nuclear forms were present and rather frequent mitotic figures were seen. In places the epithelium projected downward in short ball-like processes. In no place, however, could there be found any invasion beyond the basement membrane. This specimen was diagnosed as carcinoma in situ.

The patient was admitted to the hospital and a total hysterectomy and right salpingo oophorectomy performed. Pathological examination of the surgical specimen showed multiple intramural fibromyomas, large hemorrhagic corpus luteal cysts, a healed chronic follicular salpingitis and numerous old fibrous tags and adhesions about the right tube and ovary. Microscopic examination of the cervix revealed a thickened epithelium made up of hyperchromatic cells that sometimes lined up in spindle cell formation. There was noted considerable variation in size and shape and mitotic figures were not unusual. Large masses of this hyperactive epithelium were seen growing downward into the cervical glands. Between the cervical glands the epithelium projected downward in short downgrowths. There were also noted several large isolated islands of

epithelial cells deep in the fibrous tissue of the cervix. As the epithelium was followed laterally the evidence of invasion disappeared and the hyperactivity was found to be limited to the epithelium, that is, the surface epithelium. The appearances here were typical of carcinoma in situ. At the margin of the lesion there was a rather abrupt transition to seemingly normal epithelium. PAS technique showed the epithelium thought to be normal to contain large amounts of glycogen. At the point of transition to hyperactive epithelium there was noted an abrupt loss of glycogen. Throughout all the hyperactive epithelium there were occasional small patches of glycogen in the more superficial cells but for the most part there was a striking absence. One cervical gland showed squamous metaplasia, the squamous cells of which showed no glycogen.

DISCUSSION

Surrounding the ulcerated portion of the cervical carcinoma which stains with iodine there is a clear nonstaining zone. Schiller interprets this pale zone as identical with the lesion described microscopically as advancing margin of the carcinoma. We have shown that carcinoma in situ does not contain glycogen. In sections in which we found the normal and hyperactive epithelium demarcated by the short oblique line of Schiller, the picture is striking. If the entire thickness of the epithelium is not taken over by glycogen-free and hyperactive basal cells, glycogen is noted to be present in the more superficial cells.

In a small series other lesions of the cervix producing hyperactivity (such as regenerating epithelium) may contain no glycogen or normal amounts of glycogen in different instances. A further study is in progress. It seems possible that conditions that do not show glycogen may contain some tendency to neoplasia which becomes permanent and fixed in carcinoma.

Six of the 8 patients whose cases were studied are under 40 years of age. The average age of 35 years agrees closely with the average age reported by Schiller, and TeLinde and Galvin, being considerably below the average age of carcinoma of the cervix in general. If carcinoma in situ is actually early carcinoma then the early age at which it occurs would seem to lead to the idea that it may exist for quite some time before invasive cancer develops, as TeLinde suggests.

It is hoped that this study may suggest a new approach to an old problem, and that the findings may be of practical aid in the interpretation of some lesions of the cervix. A study of the cervical smear by the periodic acid Schiff's method is proposed while regenerating epithelium of the cervix is being reviewed in continuation of this preliminary report.

SUMMARY

The clinical and pathological features of 8 cases of carcinoma in situ are presented. Three of these are discussed in some detail.

The cases have been studied histologically and histochemically. The periodic acid Schiff's reagent technique has been applied to this material. In all cases glycogen is absent from the hyperactive epithelium. It has also been shown that glycogen can be demonstrated in formalin fixed material. The findings are discussed briefly.

SIMULTANEOUS PROSTATECTOMY AND INGUINAL HERNIORRHAPHY

DONALD F McDONALD, M D, and CHARLES HUGGINS, M D, Chicago, Illinois

AS a complication of other surgical procedures in older males postoperative retention of urine due to benign prostatic hypertrophy is frequently encountered. This is particularly common following operations for the cure of inguinal hernia. It is the purpose of this article to call attention to the fact that simultaneous herniorrhaphy and prostatectomy are well tolerated and constitute a practical procedure. Not only does the combined operation obviate an unexpected retention which frequently develops after herniorrhaphy, it also decreases the number of periods of anesthesia required to effect the desired result and usually results in a shorter hospital stay with a more rapid convalescence than when, following inguinal herniorrhaphy, postoperative urinary retention and infection develop and prostatectomy must be done. In 100 consecutive cases of prostatic hypertrophy the incidence of an associated inguinal hernia was 15 per cent.

METHODS

An analysis was made of 100 consecutive cases of prostatectomy performed on the urology service at the Albert Merritt Billings Hospital during a 12 month period. Cases were grouped according to the technique of prostatectomy used, suprapubic by Freyer's method using the hemostatic bag of Foley, retropubic by Millen's technique, perineal by Belt, Ebert, and Surber's method, and transurethral according to Nesbit. One injection of procaine spinal anesthesia was used in all but 3 cases in which ethylene and ether were employed. Further grouping was made according to operations performed at the same time as prostatectomy, and finally as to the presence of hernia and time of hernia repair with respect to prostatectomy. Herniorrhaphy was performed according to the techniques of Bassini and Halsted. Hernia repairs were al-

ways done first, and separate incisions were always made. Sealing-off of the herniorrhaphy incision with waterproof adhesive dressings was considered desirable to prevent possible contamination from infected urine.

RESULTS

Of the 100 prostatectomies 59 were done suprapubically, 54 one stage and 5 two stage. There were 35 transurethral prostatic resections, 3 retropubic, and 3 total perineal prostatectomies.

In the course of 26 of these prostatectomies 31 other surgical procedures were performed simultaneously, exclusive of bilateral vasotomy which is done routinely to prevent retrograde pyogenic epididymitis. A tabulation of the 28 cases of multiple simultaneous operations shows 5 inguinal herniorrhaphies, 9 orchietomies for carcinoma of prostate, 1 for tumor of testis, 5 excisions or fulgurations of carcinoma of bladder, 5 removals of vesical calculus, 2 hydrocelectomies, 1 hemorrhoidectomy. The maximum number of additional operations at one time was two.

The total period of hospitalization for all patients who had the one stage suprapubic prostatectomies averaged 18.8 days, for two stage suprapubic prostatectomies 28.4 days. The average period of hospitalization for patients who had simple one stage suprapubic prostatectomy was 17.2 days. In cases of one stage prostatectomy with additional simultaneous surgical procedures it was found that the average hospital stay was 18.0 days. The period of hospitalization in cases of transurethral prostatic resection averaged 8.9 days, and for radical total perineal prostatectomy it was 21 days. There were 17 cases of carcinoma of the prostate gland included in this series.

Five of the 100 patients had a simultaneous Halsted type herniorrhaphy and suprapubic prostatectomy. Four of these patients had

uneventful postoperative courses and were discharged from the hospital in 13, 15, 18, and 19 days. The fifth patient developed a myocardial infarction postoperatively and stayed 54 days. Four patients with acute retention of urine following herniorrhaphy which had been done by other surgeons were referred for prostatectomy and are included in this series of 100 cases. Three of these 4 developed urinary retention on the day of operation, and the fourth had acute retention on the eighth postoperative day. All 4 failed to respond to conservative measures and all required prostatectomy. These patients all underwent distressing periods of urinary tract infection and trials without catheter before it was agreed that prostatectomy should be done. In 1 case intolerance to the indwelling urethral catheter made a two stage prostatectomy necessary. In another the patient's poor general condition prompted delay of prostatectomy for 10 months during which time residual urine and infection persisted with distressing symptoms. The total hospital stay for these 4 patients was 16, 25, 27, and 30 days. Six of the 100 patients had asymptomatic inguinal hernias, and herniorrhaphy was not performed simultaneously with prostatectomy.

DISCUSSION

Simultaneous herniorrhaphy and prostatectomy are a well tolerated procedure and save the patient with borderline prostatic obstruction from distressing postoperative retention of urine which may follow inguinal herniorrhaphy. The patient with obstruction to the free outflow of urine may strain to void with such force that he tends to produce inguinal hernias. Thus many of the hernias seen in men of prostatic hypertrophy age may be regarded as secondary to the straining re-

quired to pass urine. Then what is more logical than correction of the primary condition, prostatic hypertrophy, and its secondary effects, vesical calculi, vesical diverticula, or inguinal hernias, simultaneously when the condition of the patient is good?

The herniorrhaphy incisions all healed satisfactorily and it was not difficult to keep the incisions clean and dry by use of waterproof adhesive dressings. Postoperative ambulation was not delayed by the multiple procedures. Patients were allowed up in a chair the first day after the combined procedure. It is to be noted that there were no deaths and only 1 serious complication in this series of 100 cases.

SUMMARY

The incidence of inguinal hernia in patients with prostatic hypertrophy was 15 per cent. In a series of 100 prostatectomies, simultaneous one stage suprapubic prostatectomy with inguinal herniorrhaphy through separate incisions was performed in 5 cases. Also there were 4 additional cases in which herniorrhaphy was followed by urinary retention necessitating subsequent prostatectomy. In most cases the simultaneous operations were followed by a smooth, rapid, and comfortable convalescence. The advantages of simultaneous herniorrhaphy and prostatectomy should be more widely appreciated.

REMOVAL OF THE AURICULAR APPENDAGE IN THE DOG

WALTER J BURDETTE, Ph D, M D, New Orleans, Louisiana

THE purpose in studying the auricle has been twofold. It stands as a portal to the interior of the heart, and, therefore, it is of interest to know the effect of surgery on this portion of that organ. In addition the auricle as well as the ventricle is involved in cardiac disease, and it is possible that operating on the auricle may be effective therapeutically in certain cases of chronic auricular fibrillation. It is important not only to know the effect of opening the auricle and removing a portion of it but also to determine how the excision may best be done. In this investigation the problem has been worked out in the laboratory, on dogs. The information so obtained should prove useful when entrance through the auricle is a portion of another operation and when the operation is used alone as well.

The auricle has been used as a route to the chambers of the heart (1, 6, 9) because the muscle is thin, because there is little danger of injury to the coronary vessels, and because displacement of the heart from its normal position is less likely. Allen and Graham (1, 2) have studied this problem in connection with their work on surgery of the cardiac valves and found that entrance through the auricular appendage was not detrimental, whereas mortality in dogs was higher when the approach was through the ventricle. However, it was not their primary purpose to devise an operation for removal of a portion of the auricle alone and to determine the effect of such a procedure.

Embolic phenomena are not unusual in auricular fibrillation. The reservoir for these emboli is the auricle, since the factors favoring clotting are operative in the auricle which is not contracting effectively. Although quinidine and digitalis are effective in many patients, it is possible that there is a group of

refractory cases with chronic fibrillation which might derive benefit from removal of the auricular appendages and adjacent auricle. After removal of the thrombus the sac in which they originate could be extirpated. It is also possible that the fibrillation itself may be altered by such a procedure (v1). This occurred to the author during the course of some preliminary experiments on intracardiac surgery at Yale University in 1943. It was not possible to start the experiment until July, 1946, however. Since that time a suitable surgical technique has been worked out for removal of the more redundant portion of the auricle which at the same time reveals the effect of using this part of the heart simply as a route to the interior.

METHODS

Adult, mongrel dogs were used. Each animal was examined and the heart sounds were noted, after which an x-ray picture and electrocardiogram were taken. This was repeated at intervals after each operation. In addition to leads I, II, III, and CF₄, the V leads were taken in a special manner with the electrode at the level of the auricle. Intravenous sodium nembutal was used to anesthetize the dogs, and an intratracheal catheter was passed and connected to a source of positive pressure which made it possible to deliver air enriched with oxygen while the chest was open. The thorax was entered through the third or fourth intercostal space, and the ribs were separated with a self-retaining retractor (Fig 1). The lungs were packed away from the field with moist gauze and the pericardium was opened. After the tip of the auricular appendage was grasped with a small hemostat, the walls of the base of the appendage including a portion of the auricle itself were sutured together with interrupted mattress sutures resulting in a linear closure. Adjacent sutures were then tied to each other, and a small incision was made in the appendage distal to the suture line. On the rare occasion when this showed

From the Department of Surgery of the Louisiana State University School of Medicine.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Los Angeles, October 18 to 22, 1948.

that the sutures were not effective, a hemostat proximal to this point stopped the bleeding and the suture line was re-enforced. This was rarely necessary. The proximal hemostat was removed, and, after bleeding had ceased, the appendage was excised. The pericardium and chest wall were closed and air was withdrawn from the thoracic cavity with a needle and syringe fitted with a three-way stopcock at the end of the operation. Respiration resumed spontaneously after the respirator was disconnected. In the postoperative period it was not found necessary to administer chemotherapeutic or antibiotic agents.

After recovery from the first operation, the appendage was removed from the opposite side. In 4 animals both sides were operated on in one stage, the usual incisions were used on either side of the chest. The animals were killed and autopsy was performed at intervals up to 2 years. Sections were taken through the stump of the auricular appendage for microscopic study, and the animals were carefully examined for signs of emboli.

RESULTS

The auricular appendage was removed on both sides in 16 dogs in 2 stages at least 2 weeks apart. All survived removal of one appendage and 15 survived removal of both. One animal died immediately after operation on the second side, probably due to an overdose of nembutal. Operation was performed on the left side first in 8 dogs and on the right side first in a similar number.

The appendages were removed at one stage in each of 4 dogs. Of these, 3 died in the immediate postoperative period, and the fourth survived. Autopsy of the 3 dogs which died revealed atelectasis and in 1 dog, pneumonia of the left lower lobe. In the fourth animal, which survived, more care was taken in removing the air from the pleural cavity at the close of the procedure than in the first 3, which died. Knowing the conditions at the operating table and the results of autopsy, it is thought that perhaps diminished aeration in the postoperative period rather than the operation on the heart itself may account for the deaths of these animals. Until further work is done, performing the bilateral proce-

dures in one stage should be viewed with some reservation, however.

In setting up the equipment for intratracheal positive pressure combined with intravenous nembutal, it was found that the addition of oxygen was necessary for best results. Also, some difficulty was experienced in calculating the proper dose of nembutal to be administered. Occasionally it was necessary to supplement the initial intravenous dose during the operation, but as the procedure became standardized and less time was required for its execution, the original amount given was usually sufficient. The operation required from 40 minutes for each of the stages in the two stage procedure to a maximum of 2 hours and 45 minutes when both appendages were removed at one operation.

The incision was at first made in the fourth anterior interspace. In some of the dogs this was slightly too low. The third interspace was used in the last half of the animals operated on, and this seemed to be too high only once. The anterior approach gave very good exposure. In the last group of 10 animals the length of the incision was about three-fourths as long as that originally used and was quite adequate. It was found most advantageous to enter the pericardium posterior to the phrenic nerve on the left and anterior to the nerve on the right because of the rotation of the heart. A removable, stay suture was used to encircle the phrenic nerve and retract it out of the way.

The type of closure of the auricular stump which first came to mind was a pursestring suture, but it did not prove useful because it required an encircling ligature to make a tight closure and the adjacent auricular wall became puckered, inviting stasis and thrombosis. Also utilization of a single suture was not as safe as a number of sutures. The procedure which was adopted proved to be quite safe, and, even though the suture line was not competent at first, this could be checked before the appendage was removed. Non-absorbable sutures were used throughout. The auricular appendage was sutured with No 0000 Deknatel braided silk. Sutures of No 00000 silk were tried but the heavier grade was found more satisfactory for this purpose.

Fig 1 After the chest is entered through the third intercostal space, interrupted mattress sutures of silk are placed through the base of the appendage and adjacent auricle. These are then tied as illustrated. A small opening is made in the appendage to test the suture line, after which the appendage is removed. The drawing shows the operation on the right side.

Less bleeding, of course, was encountered when atraumatic needles were used. The pericardium was approximated with interrupted sutures. Whether or not the pericardium was completely closed did not influence the results.

When the tip of the auricular appendage was first grasped with a hemostat, arrhythmia resulted, but lasted only a few seconds as a rule. This occurred also while the base of the appendage was being sutured but was less frequent at that time. After the operation was completed, no arrhythmia which was not present preoperatively was noted. This change in rhythm was not enough of a problem to warrant the use of procaine. Careful auscultation on numerous occasions failed to reveal the presence of any murmurs.

Since all the deaths which could be attributed to the operation occurred in the immediate postoperative period, it seems that when once the decreased volume of the auricle is established there are no detectable ill effects. Records show that all of the dogs gained

weight, which was not due to edema as proved at autopsy. One of the animals delivered a litter uneventfully after the two stage operation. It was assumed that the animal would probably survive its normal span after completing the first year without incident, and 1 dog was kept for 2 years at the end of which time no untoward effect from the operations was found. When the operation was done in two stages, all of the animals survived the first stage and it is reasonable to suppose that incision or removal of the right or left auricular appendage would carry little or no mortality except that connected with extracardiac complications.

Autopsy showed that the parietal pleura invariably became adherent to the visceral pleura at the point of entrance into the thoracic cavity. The pericardium was adherent to the lung at the suture line. Fibrinous adhesions between the pericardium and auricular stump also occurred in the animals, but adhesions to the base of the ventricle were

Fig 2 Endothelial surface of both auricles following removal of both appendages illustrating satisfactory healing

Fig 3 External suture line on the same heart as is shown in Figure 2

seen in only 2 animals. In all cases the auricular stump was well healed, and the luminal surface was smooth, glistening, and covered with endothelium (Figs 2 and 3). No antemortem thrombi were found within the heart. Microscopic sections showed the presence of a well healed scar with no sign of inflammation near the endocardium (Fig 4). There was some reaction around the silk which remained and consisted of an infiltration of small and large round cells. An interesting finding was the presence of considerable cartilage in two of the scars from different animals and bone in a similar number.

There were no signs of cardiac failure. The average weight of 10 of the hearts was 101.4 grams. The average, maximum thickness of the wall of the right ventricle was 7.4 millimeters and that of the left was 13.1 millimeters. The corresponding average, minimum thicknesses were 2.7 millimeters and 5.9 millimeters, respectively. This fact indicates that there was no hypertrophy, and examination of the organ showed no dilatation. The liver appeared to be normal, and there was no accumulation of fluid within the tissues or body cavities at the time of autopsy. Examination of the abdominal and thoracic viscera as well as section of the brain failed to reveal any evidence of infarction due to emboli. Autopsies were done on 3 dogs which died in the im-

mediate postoperative period, the remaining autopsies were performed from 3 months to 2 years following operation.

The average weight of all right appendages removed was 756 milligrams and of all left appendages was 704 milligrams. The respective averages for the last 10 operations were 830 milligrams and 677 milligrams for right and left appendages. This represents 1.49 per cent of the average weight of the heart. In the early operations a greater amount of left appendage was removed, but later it was possible to remove more of the right auricular appendage including a portion of the auricular wall.

Roentgen studies before and after operation showed no change in contour of the heart in posteroanterior views. However, more detailed studies were not done and may possibly have shown the defect after operation. Certain electrocardiographic changes were noted. There was diminution of the *P* wave in limb lead I and also in the special *V₃*, *V₄*, and *V₅* recordings. The negative deflection in leads *V₁* and *V₂* was decreased after removal of either or both auricular appendages. Care was taken to have the dog in the same position each time. A special study of the contribution of the auricular appendage to the electrocardiogram is being made and will be reported subsequently.

After this work was completed (5) the studies of two other groups came to our attention. Madden, at the suggestion of Dock, removed the left auricular appendage in 2 patients, one of whom died. Hellerstein and associates amputated the appendage in the dog, using a clamp and a ligature in all except 2 dogs. They reported no constant electrocardiographic changes except a transient intra-atrial block.

DISCUSSION

The results which have been obtained in this group of animals indicate that opening or even excising the auricular appendage on one side results in no demonstrable deleterious effect. It is well known that wounds of the ventricle may result in serious or even fatal consequences due to injury of the blood supply to the ventricular muscle. In addition, the closure of the ventricle presents a greater problem than closure of the auricular wall. However, Cutler and coworkers (7), on theoretical grounds, chose the ventricle as the site for introduction of the cardiovalvulotome in correcting mitral stenosis. They felt that because of increased pressure and dilatation of the auricle in mitral stenosis there would be danger of dislodging thrombi and tearing the distended wall. In a later paper (6) they say that further attempts through the auricle are justified and report that this approach was used in 3 of their cases because exposure was easier and less difficulty was encountered in guiding the tip of the instrument through the mitral orifice.

The results obtained in this experiment and those of Allen and Graham (1, 2) indicate that in approaching the interior of the heart for the purpose of correcting congenital anomalies or the effects of disease, the auricle is a route of choice. Harken and coworkers have also found it a better approach to the mitral valve than is the ventricle. At the present time such an approach has been attempted sporadically and without brilliant success because time is a limiting factor, visibility is poor or nonexistent, and special instruments are necessary. Certainly extracardiac reconstruction (3, 4, 14, 15) is safer and offers more at present than surgery within the heart it-

Fig 4 Section through the stump of the auricular appendage showing endothelium covering the scar $\times 115$

self. However, this does not mean that the problems of intracardiac surgery are insurmountable, and it may become useful when more is known about the possibilities of circumventing the present difficulties with such surgery (8).

Auricular fibrillation is still a problem for the cardiologist, and perhaps the operation just described may have some application to the treatment of this disease. The treatment of fibrillation with quinidine is not altogether successful, and at times even if there is conversion to normal rhythm, emboli are dislodged. Anticoagulant therapy cannot be continued indefinitely, and of course thrombi already formed are not affected by such treatment. With no desire to alter or detract from treatment which is effective, it is reasonable to suppose that the operation described could help patients who do not respond to medical therapy. This work on the dog would indicate that it is possible first to remove thrombi and then to eliminate the reservoir in which the clots are formed by removing the portion of the auricle harboring them.

The operation proposed in the human would be to open the tip of the appendage and remove any clot present and then to use a hemostat both for closing the opening and for traction. After the row of sutures at the base of the auricular appendage is completed, as described for the dog, a small opening between hemostat and sutures or simply the release of the hemostat would indicate whether

a competent suture line were present. If bleeding occurred, the distal portion could be clamped again and the closure completed. The appendage would be removed only after the operator was certain the lumen of the auricle had been completely closed. It might be necessary to modify the method in the presence of mitral stenosis with a distended and thin left auricle, but by no means is this situation encountered in all cases of mitral stenosis (9).

Fibrillation is a continuous circus movement usually with a main pathway around the origin of the great veins. A wave of contraction progresses along this pathway, limited in its direction by the refractory period of the muscle, and perpetuated by an excitable strip ahead. Conditions which alter the situation and favor stopping the circus movement are a shorter pathway, more rapid conduction, and a longer refractory period (11, 12). Quinidine and digitalis are effective because they affect the refractory period and the conduction time. Removing a part of the auricular muscle conceivably could stop the fibrillation as well as remove the source of emboli by producing a shorter pathway. Theoretically, alternate longer circuits could be eliminated and even if the operation did not produce the desired results alone combined with quinidine it could add enough to the total situation for a favorable result. Unfortunately, it has not been possible to test this hypothesis in dogs. There is otherwise sufficient justification for the procedure in man, however, and the question as to whether the fibrillation itself will be altered can be determined in that manner.

The portion of the auricle removed at such an operation could serve a very useful purpose. Cardiac muscle has been studied extensively in other forms but for very obvious reasons there is no source for studies of metabolism, etc in man. Any muscle removed

should be utilized for that purpose and might help clarify some of the fundamental problems in human cardiac physiology and its alteration in disease.

CONCLUSIONS

1. A method for safely removing the auricular appendage in the dog has been devised.

2. All of 16 dogs survived the first of two stages and 1 dog died within 12 hours after the second stage of the bilateral auricular excision. This death was probably due to an overdose of nembutal.

3. Only 1 dog of 4 survived when the auricular appendages were removed in one stage. These deaths followed pulmonary complications in the immediate postoperative period.

4. Electrocardiographic changes occur after operation.

5. This operation has certain therapeutic possibilities in man.

SOME ASPECTS OF THE DEVELOPMENT OF INTRATHORACIC SURGERY

CLARENCE CRAFOORD, M D, Stockholm, Sweden

IN this, the third Martin Memorial Lecture, it is my purpose to present some of the main problems encountered in the surgical service of the Sabbatsberg Hospital in Stockholm in the development of thoracic surgery. One problem, always of special interest to me, has been that cardiorespiratory dysfunction is encountered immediately upon the opening of the chest.

FACTORS INFLUENCING THE DEVELOPMENT OF THORACIC SURGERY

Why has the development of major intrathoracic surgery been delayed several decades while that of general surgery has progressed? The most important causes of this delay I believe are lack (1) of adequately trained specialists, (2) of adequate teamwork, (3) of means of securing adequate anesthesia, (4) of knowledge concerning chemotherapy, and (5) of knowledge concerning cardiorespiratory disturbances produced by thoracotomy.

1 Thoracic surgery presents so many difficulties that I think we all agree it is necessary to entrust this branch of surgery to specially trained men. It is obvious that since this practice has become more and more the custom, the rapidity with which improvements in technique have developed has increased considerably.

2 In the early decades of this century, the importance of teamwork was little appreciated. The rapid advancements in medical science have made it evident that close cooperation between highly trained specialists in the different branches of medical practice is today even more necessary to secure further advancement. This is especially true regarding thoracic surgery.

3 A third factor in the delay in the development of thoracic surgery has been, without doubt, insufficient means of securing anesthesia. Not only has thoracic surgery but so also has every field in advanced surgical practice benefited enormously from the rapid strides made in anesthesiology, emanating from the Anglo-American countries and especially from the United States.

4 The fourth factor, the introduction of chemotherapy, has also in my opinion accelerated development and has been of significant value in thoracic surgery. In certain infections in which previously prognosis was very bad, patients can now be treated radically without undue risk.

5 There can be no argument regarding the fact that great importance in the delay in the development of thoracic surgery must be ascribed to insufficient knowledge of how to correct cardiorespiratory disturbances occurring immediately the thorax is widely opened.

Like many other specialties, thoracic surgery has branched off from the original family tree, general surgery, to become an independent specialty. Well trained general surgeons with a keen interest in exploring new fields were the first to attack thoracic surgical problems. While such workers achieved isolated brilliant results which demonstrated the potentialities in this branch of surgery, they were not able to repeat successfully in sequence the desired results because they did not fully appreciate the factors which are here outlined. Achievements by men such as Matas, Willy Meyer, Lilienthal, Torek, Graham, Meltzer, Auer and Elsberg, on this continent and by such men as Tiegel, Friedrich, Sauerbruch, Trendelenburg, Tufner, Rehn, Giertz, Delorme and Garre in Europe have later stimulated general surgeons interested in chest surgery to continue their efforts. During this period the importance of different factors afore-

The third Martin Memorial Lecture of the American College of Surgeons presented before the Clinical Congress of the American College of Surgeons, Los Angeles, California, September 18 to 22, 1948.

mentioned have gradually become increasingly recognized

SPECIAL TRAINING IS NECESSARY

A number of general surgeons soon realized that to achieve success in this branch of surgery they must devote themselves entirely to chest work. Special chest services have gradually been established and increasing numbers of younger men have devoted themselves to this specialty in an effort to obtain adequate training. Centers for the treatment of thoracic diseases have been established in many places in this country and in Europe. In Sweden we shall, in the near future, erect in connection with the University of Stockholm a separate hospital building exclusively for the treatment of chest diseases. It would thus seem that the lack of adequately trained surgeons specializing in thoracic diseases will be overcome in the very near future.

In this connection a new problem arises. How is the training of the younger men to be most satisfactorily arranged? I am definitely of the opinion that every chest surgeon must have as thorough training in general surgery as any man who wants to become a general surgeon, the training in thoracic work must be superimposed or added to his general surgical education. An additional short period of laboratory work should also be required. Some training in anesthesiology, in the use of the x-ray, in bronchoscopy, and in internal medicine is essential. With knowledge founded on such an education, I believe that the thoracic surgeon would be qualified to take up independent work in his special field.

It has been my observation that there is a tendency among the younger generation of surgeons who intend to specialize to commence practice without a broad foundation on which to stand. This tendency, I believe must be strongly opposed if a sound basis for successful practice is to be attained.

TEAMWORK

The second factor delaying progress in the development of thoracic surgery has been the previous lack of teamwork. In the medical profession co-operation or teamwork, had been rather unpopular until shortly before

World War II. For the most part our scientists have been "lone wolves" in their scientific work. The recent rapid development in the various branches of medicine has brought about a demand for collaboration, since it is often impossible for one single man to master even his own special field. In this respect also the United States has taken the initiative and has shown the world that close co-operation between skilled scientists in different fields is often necessary to obtain desired results within a reasonable length of time. For the solution of many problems in thoracic surgery we need the help of representatives well trained in the basic sciences as well as the help of members of the different branches within the medical field, for example, in the treatment of congenital heart malformations, the close co-operation between the surgeon, the x-ray specialists, the cardiologist, and the pediatrician has been invaluable in the development of this highly specialized form of therapy. To obtain accurate and practical equipment both for the diagnosis and for the actual surgical work the advice and help of theoretical institutions and of a skilled engineering department have been indispensable, to me at any rate.

In developing a team it must be borne in mind that many scientists are inherent individualists with strong will power. These qualities might be more pronounced in one member of the team than in others and he with the strong will power will probably be the organizer and leader of the team. It must therefore be emphasized that in every team each member has his part to play and that the contribution of each is necessary to accomplish the result, credit for the solution of a problem is due the team as such, not to any individual of the team. Should one member of the team take undue credit to himself, bad feelings can easily be aroused within the team, thus reducing its working capacity with loss in subsequent output.

ANESTHESIOLOGY

Considerable progress has been made in anesthesiology during the period in which thoracic surgery has been maturing into an independent specialty. Improved equipment and methods of inducing anesthesia as well

as new drugs have been of great benefit in thoracic surgery; it is my opinion, however, not so much the better equipment and the anesthetic agents but the method of their administration that has been helpful in securing better results in this branch of surgery. Another and most important factor is that qualified doctors are trained to be skillful specialized anesthetists who give their personal attention to every detail in often very long drawn out anesthetics necessary for difficult chest operations. One fundamental factor, however, remains amazing to me, namely, that the problem of how to correct continuously and effectively the disturbances in respiration in an open chest operation is not yet consciously and fully appreciated by the vast majority of our anesthetists and thoracic surgeons. This question will be discussed in some detail later.

CHEMOTHERAPY

The importance of chemotherapy, i.e., the use of the sulfa drugs, penicillin and streptomycin, separately or in combination, has been much discussed. Some authors believe that the value of these drugs in chest surgery has been overestimated. From my own experience I am of the opinion that the vast majority of infectious complications connected with thoracic disease are favorably affected by chemotherapy regardless of whether the complication preceded or followed operation. Chemotherapy has accelerated the development of the surgical treatment of infected chest disease and patients who previously could not be treated can now be given the benefit of surgery. Another fact worth mentioning is that chemotherapy has reduced to a minimum one of the most discussed technical problems in lung surgery, namely, the treatment of the bronchial stump after lung resection. Before the era of chemotherapy, in order to secure the lowest possible percentage of complications without fistulas in the healing of the bronchial stump, I found that a lengthy, somewhat difficult and meticulous technique, described by me in 1939, was necessary. Now, with chemotherapy, even though comparatively crude methods of closure of the bronchus appear to give satisfactory results I still

Fig 1 Alterations in respiration in open chest during inspiration, a, and expiration, b,

prefer my old meticulous technique which I consider to be the safest.

CARDIORESPIRATORY DISTURBANCES

Finally I come to what I regard as the most important factor in the delay in the development of thoracic surgery, the lack of adequate knowledge concerning cardiorespiratory disturbances produced when the chest is opened.

In 1939 I had the privilege of presenting here in Los Angeles to the American Association of Thoracic Surgery my views of respiratory disturbances in the open chest and how to overcome them. During the last decade the principles outlined at that time have been consistently followed in my clinic and we have never had occasion to change them. On the contrary accumulated experience has further convinced me of the superiority of our method over that of others. I shall briefly review the basic physiological changes in respiration when the chest is opened.

The diagrams in Figure 1 show the well known alterations which occur. In a, is shown the gas flowing from the outside through the trachea into the unopened thorax during the inspiratory phase of respiration. During this phase as the thorax expands the negative pressure on this side is increased which accounts for the flow in this direction. In addition, and because of the same negative pressure, one also finds gas from the opposite lung flowing into the lung on the unopened thorax, the mediastinum is pulled to this side and thus the volume of gas (tidal flow) flowing into this lung is reduced.

During expiration (Fig 1 b) the dynamics are reversed. The intrapleural pressure in the un-

Fig. 2. Apparatus to oxygenize the blood. 1, Tube conveying venous blood, 2, flow meter, 3, the oxygenator, 4, tube in front of a photoelectric cell, regulating the speed of the pumps and thereby also the level of the blood, 5, pulsator, 6, tubes to the pumps, 7, the pumps, 8, contact thermometer, 9, manometer for blood pressure reading, 10, tube to the arteries.

opened thorax becomes less negative or even positive as the muscles of expiration contract. The gas leaving the lung on the unopened side goes in two ways as it reaches the bifurcation of the trachea, most of it into the trachea, a smaller part into the opposite lung (pendulum air). The result of this is that since the patient is breathing essentially with only one lung, the abnormal ("paradoxical") flow of gas and the abnormal ("paradoxical") movement of the mediastinum reduces tremendously the respiratory efficiency of that one lung. It follows, therefore, that the softer and more pliable the mediastinum the greater is this reduction.

In this connection it is interesting to note that prior to the endeavor to correct these disturbances of respiration in the open chest, only relatively few cases of successful intrathoracic operations were reported. It is true however that during the same period abdominal surgery had been rapidly progressing and large series of successful operations had been re-

Fig. 3. Many small discs which rotate within cylinder in which blood is collected for oxygenation.

ported. By contrast, the fact remains, however, that surgical procedures below the diaphragm produce few significant cardiorespiratory changes.

Ferdinand Sauerbruch, one of the pioneers in thoracic surgery, was one of the first in Europe to understand the importance of correcting respiratory disturbances in the open chest. He was the first to develop a method for performing thoracic operations under continuous negative pressure and later on a method for the use of continuous positive pressure. My compatriot and former chief and teacher, Dr. K. H. Giertz, showed in 1914 to 1916 in thorough experiments on large dogs that from the physiological point of view there is no significant difference in cardiorespiratory efficiency between either the negative or positive pressure methods. At the same time he very clearly and conclusively demonstrated that rhythmic insufflation during the inspiratory phase of respiration and free outflow of the gas from the lungs against normal atmospheric pressure during the expiratory phase is superior to all other methods used to correct the respiratory disturbances in the open chest. This fact was already touched on by Matas in 1901.

The rapid development of thoracic surgery during the 1930's is above all due to the more and more extensive use of this type of respiration. This progress was attained regardless of whether the control of respiration was brought about mechanically, by the use of specially

Fig 4 Diagram showing method of oxygenation

constructed machines such as the spiropulsator that we always use, or by hand by the anesthetist rhythmically compressing the anesthetic bag. Visits to a great number of chest centers at different times during the 1930's and 1940's establishes the fact that now the use of controlled respiration is becoming increasingly widespread. Nevertheless I consider the use of a machine for this purpose to be much safer and more reliable than any other method. It is possible with such a device to create rhythmical artificial respiration for an unlimited length of time at a rate and with a gaseous exchange that closely simulates normal physiological breathing. I am convinced that with the increasing use of curare in intrathoracic anesthesia a machine like the spiropulsator will become more necessary. I am glad to see that more thoracic clinics are adopting our method, with satisfactory results.

If one endeavors to correct the altered respiratory conditions in thoracotomy cases by using an ordinary positive pressure machine with constant flow, the mediastinum will be stabilized within certain limits by the positive pressure alone, but the flow of the so called pendulum gas between the lungs will continue. My impression is that the amount of the pendulum gas is certainly greater than is generally believed, in the case of thin walled big cavities I have been astonished to see how large the gas volume really is.

Ordinary positive pressure works to very great disadvantage in that it increases the diffi-

Fig 5 Mechanism of pump

culties of expiration. As you know, the expiratory muscles are not very well developed in man. Attempts to expire for a considerable length of time against slight positive pressure, will soon cause fatigue. I have found that expiratory difficulty results in an increase of carbon dioxide in the blood, after a certain length of time, and acidosis develops due to gradually increasing expiratory deficiency. The expiratory muscles endeavor as long as possible to overcome the increased expiratory resistance, but after a varying length of time, in different persons, fatigue makes them unable to fulfill the requirements for proper expiration even though low positive pressures are used. As the expiratory muscles become exhausted, the patient breathes with a more and more expanded thorax. In order to diminish these expiratory difficulties, it is generally considered that as low a positive pressure as possible should be used, on the other hand, with a low positive pressure there is more extensive paradoxical motion of the mediastinum, with all the consequent disadvantages of this motion.

If the tidal volume is insufficient, anovemia increases, and there is an increase in carbon dioxide in the blood. I am convinced that unless respiration is controlled the patient has a very small margin of safety since ventilatory exchange is then poor. In the majority of patients whom I have had the opportunity of observing in different chest clinics where controlled respiration is not used, the work of the respiratory muscle has been considerably increased during operations upon a patient's wide open chest cavity. Many times these respiratory movements have been increased to such an extent that they have been exhausting to the patient. In my opinion, however, this strained respiration adds considerably to the respiratory burden, since the muscular work

in itself increases the demand for oxygen and so a vicious circle is established

In my opinion it is not an exaggeration to state that in the use of mechanically arranged artificial respiration which simulates normal breathing when the chest is open, we are in possession of the most ideal method for ventilation during these operations. It gives the widest possible margin of safety and also permits the performance of very difficult and time-consuming intrathoracic operations without the necessity for haste.

The validity of this conclusion is confirmed not only by the large series of intrathoracic operations now reported from different clinics, but also, and perhaps still better, by the great improvement in results obtained by surgical treatment of thoracic injuries in World War II over World War I. Sauerbruch, who erected special surgical chest services close behind the fighting lines on the western front at the end of World War I, was unable to bring the mortality rate lower than about 20 per cent. In the American Army, where intratracheal intubation and controlled respiration, to my knowledge, were practically always used during World War II, the primary mortality was brought down to about 5 per cent. The use of more effective antishock treatment and of chemotherapy have naturally helped to decrease the mortality rate, but the use of adequate ventilation during operation in these cases has certainly been of great importance in bringing about improved results.

Another small group of patients operated upon also proves the importance of adequate ventilation during operation within the chest. Since Trendelenburg in 1908 experimentally showed the possibility of removing large emboli from the pulmonary artery, a considerable number of such patients were operated upon in Germany, but always with fatal result. All patients were operated upon through the opened left pleural cavity and with ordinary constant flowing positive pressure. In 1924 when this operative procedure had lost its foothold, the German surgeon Kirschner succeeded in removing a large embolus from the pulmonary artery and the patient survived. This success produced a new wave of activity but the results were as unsatisfactory as be-

fore. In 1927 A. W. Meyer, of Berlin, changed the technique to a transmediastinal approach without opening either pleural cavity and was able to report 4 successful cases within a short period. Using the same technique, Professor Nystrom, of Upsala, and I successfully performed pulmonary embolectomies in 7 patients. At that time I did not realize that it must have been the added demand on the function of the lungs and heart when operation was done through a transpleural incision without controlled respiration that explained the consistently high mortality; it was the improvement in function of the lungs and heart when operating transmediastinally that changed the prognosis.

In my clinic we have now started an investigation concerning the alterations in pulmonary arterial pressures under varying conditions. At the same time blood chemistry analyses are made and the cardiac output is determined. One of our aims is to learn how these factors vary when different types of ventilation are used during anesthesia in open chest operations. The evidence so far obtained does not permit definite conclusions. It would seem, however, that completely controlled artificial respiration maintains the normal pressures within the pulmonary artery, whereas continuous positive pressure breathing or spontaneous breathing with only small or no help from the anesthetist produces a very marked drop in this pressure followed by diminished cardiac output.

Intracardiac surgery has also had its problems. It is easy to understand that complete control of all respiratory disturbances is a prerequisite to the intricate steps of intracardiac surgery. Operations which do not hamper the heart action too much cause few respiratory problems—it is possible to remove foreign bodies from the heart in many cases and to operate successfully on some congenital malformations as well as upon the pericardium. However, if the heart function is disturbed too much by an operation close to or within the heart itself, it is my firm conviction that some means of replacing the heart action must be provided and that this is best done with some machine that can produce extracorporeal circulation, and at the same time

oxygenate the blood This, I believe, will be as important in securing good results in intracardiac surgery as has been the replacement of the patient's own breathing by mechanically controlled respiration in the development of ordinary intrathoracic surgery

In seeking a solution to this problem we have fully realized the great difficulty of constructing a machine with such capacity that it could take over the entire burden of the heart and at the same time be able to oxygenate enough blood for the needs of a large animal or of man We have, therefore, concentrated our efforts on devising a machine which could take over only the more vital demands upon the heart The most urgent demand on the heart, from a point of view of time, is made by the central nervous system, which cannot withstand deprivation of its arterial blood supply for more than 4 to 5 minutes without irreversible damage to the nerve cells It was my opinion, therefore, that if, during an operation upon the heart, satisfactory circulation could be artificially supplied to the brain, it would be possible to cut off the entire supply of blood to the heart, with the possible exception of the coronary circulation Operation then could be performed quietly and without haste and when completed the heart could once more take over the entire circulatory processes and the artificial cerebral circulation could be eliminated

Other organs of the body can be cut off from arterial circulation for a much longer period of time as was shown in a special group of cases of patent ductus arteriosus in which I performed division and suture of the large vessels In these cases—now 33 in number—the aorta was completely clamped, distal to the subclavian artery All arterial circulation was thus inhibited with the exception of that supplied by the large vessels originating directly from the arch of the aorta The time of clamping varied between 10 and 27 minutes, in the majority of cases for 20 to 25 minutes In none of these cases were there discernible disturbances in those organs supplied by arteries originating below the site of aortic occlusion In one other case technical difficulties unfortunately prolonged the time of occlusion to between 45 and 50 minutes In this case al-

though signs of circulatory disturbances in the spinal cord became apparent they were in the process of regression 3 weeks later when the patient died from another cause It thus seems that the collaterals to the spinal cord from the vertebral arteries are not adequate to maintain function for so long a period of time It appears, therefore, that we should have a period of approximately 25 minutes for surgical procedures within the heart itself with simultaneous inhibition of all blood supply to it, provided that artificial circulation can be supplied to the central nervous system during this period

In close co-operation with Mr Emil Anderson of Aga's experimental department and with Dr Viking Bjork, who during recent years has been my scientific assistant, and through generous financial grants from the Swedish Technical and Medical Research Councils, it has been possible for us to solve experimentally the problem of artificial cerebral circulation Mr Anderson has worked on the difficult technical problems of engineering construction To Dr Bjork was entrusted the task of analyzing the perfused blood in every conceivable way during the experiments The results of his analyses have gradually given rise to changes in the apparatus and the techniques of perfusion until at last we have reached the stage where it is possible to relieve the heart from its task of supplying the brain with oxygenated blood

The idea of constructing an apparatus for perfusing the organs with oxygenated blood is far from new Ever since Ludwig and Schmidt in 1868 attempted to add oxygen to the blood for the purposes of perfusion, simply by shaking the blood in the air, a number of workers have tried to solve the problem in various ways Nevertheless, until the end of the 1930's, no one had succeeded in constructing an apparatus in which alterations in the blood (hemolysis, coagulation, etc) were reduced to such an extent that in the presence of adequate oxygenation irreversible organic changes did not develop in the experimental animal John Gibbon Jr, of Philadelphia, was the first to succeed, by means of artificial circulation, in keeping his experimental animal—in this case a cat—alive for a prolonged

period Four cats, which had the pulmonary artery clamped for periods of 12 to 20 minutes, survived and were healthy His experiments have been resumed since the close of World War II

Earlier attempts to supply oxygen to the blood to be perfused were chiefly made in three different ways The first was to bubble oxygen through the blood The second consisted in an attempt to split up the blood into small drops in an oxygen atmosphere and then to recollect the blood The third method was to spread the blood in a very thin film over a large surface The last mentioned method was that used by Gibbon and he succeeded in supplying a greater quantity of oxygen per time unit than any other previous worker had done With a rate of flow of 400 to 500 cubic centimeters per minute through the apparatus, he was able to supply 30.5 cubic centimeters of oxygen per minute to the blood flowing through it This quantity of oxygen is nevertheless far from sufficient to respond to the needs of the human brain, which has been calculated to require between 90 and 100 cubic centimeters of oxygen per minute

In the lungs of mammals, the red blood corpuscles are exposed to the oxygen in the alveoli only for a very short time—even less than one second This length of time more than suffices, however, for the hemoglobin in the corpuscle to become saturated with oxygen, even if its original oxygen content was very low We considered that it was worth endeavoring to imitate this actual condition when constructing our apparatus through which the blood must flow in passing from the superior vena cava to the arteries which supply the brain

We, therefore, built an apparatus in such a way that the blood flowing through it is repeatedly and at short intervals brought up and spread out on a series of thin circular discs which are partially dipped into the blood flowing through the apparatus Figure 2 shows the apparatus for experimental use

The apparatus consists of a number of principal parts First, the artificial lung or oxygenator (3 in Figure 2) and, secondly, the artificial heart or pulsating pump (7 in Figure 2) Oxygenation is achieved by collecting the

blood from the venous system of the experimental animal in a recumbent half cylinder Many small circular discs on a rotating axle fit into this half cylinder (Fig 3) By rapid rotation of these discs, a thin blood film adhering to them is exposed to an atmosphere of oxygen (Fig 4) The optimum minute area of blood film exposed to oxygen in our present machine is about 50 square meters—in other words, an area equal to a fair sized room The oxygenated blood which amounts to approximately $\frac{3}{4}$ of a liter per minute and to which can be added 70 to 80 cubic centimeters of oxygen is recollected and distributed to the experimental animal by a rhythmical pumping system This system consists simply of two modified de Laval pumps for milking cows The pump consists of a metal cylinder lined with a rubber cuff (Fig 5) The rubber tube conveying the blood passes through the center of this cuff and is rhythmically constricted by compressed air Valves on each side of the pump keep the blood flowing in only one direction There are two such pumps working parallel with alternating pulsations simulating systole and diastole and producing a blood pressure consistent with that found in the experimental animal

It is not, however, sufficient to saturate the blood that passes through the perfusion apparatus with oxygen before it is retransferred to the arterial system of the animal The blood to be delivered must be controlled in every possible way to ensure that it is as similar as possible to normal blood Frothing must be prevented else emboli may occur Heparin is used to counteract the clotting mechanism of the blood The carbon dioxide content must be kept constant in order to maintain the desired pH The blood sugar which has proved to be very unstable must be replaced Any tendency to hemolysis must be avoided and the temperature must be automatically kept at a constant normal level for the experimental animal These and still other less important factors all must be controlled in order for the blood to be serviceable¹

We have now reached the stage where, by our perfusion method, after clamping the

¹(Further details are given in *Acta chir scand* 1948 Vol 96 suppl. 137)

brachiocephalic artery in the dog and ligating the vertebral arteries, we are able to keep the brain alive for as long as $1\frac{1}{2}$ hours. The blood from the artificial heart and the oxygenator is injected into the carotid arteries through the brachiocephalic and removed from the superior vena cava which is clamped proximally during the experiment. In our series of perfusion experiments we have also performed one on a dog, in which a right sided thoracotomy was done, the azygos vein was ligated and both cavae were clamped. Thus in this animal no blood from the systemic circulation was permitted to enter the heart and the only circulation which was maintained was the artificial brain perfusion. The cavae were clamped and the perfusion was maintained for 33 minutes. This animal survived and has been under observation for more than a year without any signs of damage.

During the last 3 months we have performed intracardiac operations on a small number of dogs but have not yet obtained successful results. Some dogs have survived from 1 to 10 hours. They have regained normal eye reflexes, moved their legs, made attempts to stand up, and have also discharged normal urine. During the time of survival they have shown a decrease in the blood pressure and an increase in the pulse and respiratory rate. In the majority of cases hemorrhage was found in the pleural cavities at autopsy. The cause of death was considered to be an excessive loss of blood. This bleeding is certainly due to the comparatively large dose of heparin necessary to avoid coagulation in the extracorporeal circulatory circuits.

We are now trying to diminish the amount of heparin as much as possible, we cover all surfaces in contact with the blood outside the body of the dog with a new plastic material named silicon and try to ascertain the adequate doses of protamine sulfate necessary to

neutralize the heparin in the blood of the experimental animals.

A number of dogs have also died of ventricular fibrillation. Following the suggestions of Dr. Beck, of Cleveland and Dr. Fauteux, of Montreal, we have been able to overcome this complication mainly by the use of their method of electric shock treatment of the heart.

We had hoped that once we had solved the problem of the safe perfusion of the central nervous system, which we had expected to be the main difficulty in attacking the bloodless heart, we should no longer be faced with any other major problem. This, unfortunately, so far has not proved to be the case, a number of unknown factors concerning the reaction of the heart itself still must be analyzed successively before intracardiac surgery can be fully developed.

To my knowledge this study is in progress at present in five places, i.e., in Philadelphia, in Minneapolis, and in Toronto on this Continent, and in Europe in Holland and in Sweden. One achievement that seems probable in the near future is the study of the metabolism of isolated organs in the living animal. Another is concerned with the possibilities to be anticipated when oxygen can be supplied temporarily by perfusion in order to supplement inadequate oxygenation on the part of the lungs.

I have attempted to set forth the present status of the development of thoracic surgery and have offered some suggestions concerning its further evolution. I have also outlined the evolution of controlled respiration and its significance in thoracic surgery. I hope I may be pardoned for attempting a parallelism between this and the development of what might be termed controlled circulation for I feel sure that here lies the solution of the problem of intracardiac surgery of tomorrow.

A SIMPLIFIED TREATMENT OF INGROWN TOENAIL

R. W. NEWMAN, M.D., F.A.C.S., Iowa City, Iowa

INGROWN toenail pathologically is a minor lesion, but symptomatically it is a major ailment. The cause commonly is an abnormality, not of the nail but of the soft tissues, of which there is an excessive growth at the end of the nail which obliterates a portion of the nail sulcus in which the lateral edge of the nail normally rests. It results from a combination of faulty trimming of the nails and crowding of the toes in ill fitting footwear. Treatment directed toward the soft tissue overgrowth should logically correct the ailment.

The widespread and commonly accepted treatment of this condition deals with the nail, a small strip of which extending from free end to root is removed with matrix.

The following treatment, dealing with the soft tissue only, corrects the underlying cause, is simple and rapid of performance, and yields prompt and permanent results. It may well be considered an office procedure.

It was first employed on troops aboard ship during maneuvers in preparation for the invasion of Sicily. It has since been used on a large number of patients by the author and his colleagues. The results have been uniformly satisfactory. Its object is to reestablish and maintain the nail sulcus and thus to provide the nail an open channel along which its growth may proceed unobstructed. This involves an incision through the soft tissues under novocain anesthesia and the application of a small metal plate with an under turned edge. An extensive inflammatory reaction should be cleared up by frequent hot soaks previous to surgery. The procedure is carried out without hesitancy in the presence of chronic well localized infection. The plate provides excellent drainage.

THE OPERATION

The toe is prepared for surgery by the liberal use of soap and water, alcohol and an antiseptic such as tincture of zephiran or mercuriolate. A small quantity of novocain is in-

jected directly into the swollen prominent soft tissue over the tip of the ingrown portion of the nail at the end of the toe (Fig. 1, A). This is injected rapidly and under sufficient pressure to insure immediate anesthesia and provide absolute hemostasis. An incision is then made directly down through the overgrown soft tissues in line with and about the depth of the nail sulcus, revealing the lateral margin and the ingrown tip of the nail (Fig. 1, B). The nail plate (Fig. 1, C) is now put in place by first engaging the narrow, underturned margin beneath the ingrown tip of the nail and then gently forcing the plate proximally on the nail (Fig. 1, D and E). It is not necessary to push the plate beyond the eponychium, for there is sufficient lateral nail margin remaining distal to this point (Fig. 1, B) to hold the plate securely. The free or distal end of the plate is allowed to project beyond the soft tissue at the site of the incision. This insures the formation of a normal nail sulcus along which the nail will eventually grow. The plate is held in place by two narrow pieces of adhesive tape (Fig. 1, F). It is essential that the tape be merely laid on, care being exercised not to subject the swollen soft tissue flap adjacent to the plate to undue pressure. A sterile piece of gauze is then applied and secured with narrow bandage and tape.

This entire procedure can be carried out in several minutes and well within the period of hemostasis afforded by the pressure injection of the novocain.

The patient is permitted to bear weight immediately. The toe ordinarily remains sore for 2 to 3 days. At the end of this time the patient may be expected to become normally active. If appreciable soreness persists beyond 3 days, the plate should be carefully inspected. It may become slightly displaced and cause undue pressure on the sensitive nail fold adjoining the eponychium. Care in properly placing the plate and the tape at the time the operation is performed will avoid this complication.

The first plates to be used were cut from a grapefruit juice can. There was slight reaction between the plate and open wound as manifested by the formation of a dark brown deposit on the plate and the nail. This apparently interfered in no way with the healing of the wound. Plates of lightweight duraluminum were next used. These were quite satisfactory and caused almost no reaction. At the present time plates of stainless steel are employed and these are recommended. They are entirely inert in tissues. A stock of these, cut to 3 sizes, are kept on hand. Before preparing the toe for surgery, the plate nearest the size desired is selected and trimmed to the exact dimensions required, and then placed in an antiseptic solution preparatory for use. It is so cut that the free or distal end runs from the tip which is to project beyond soft tissue at the nail sulcus obliquely back or proximally at an angle of about 60 degrees (Fig 1, C). This allows a portion of the distal end of the nail to remain exposed. A small area of the nail opposite the side involved is likewise left uncovered (Fig 1, F). This serves for simplicity in securing the plate with tape and in keeping the area clean.

AFTER CARE

The outer gauze dressing should be changed on the third day. The toe is cleaned and a small piece of sterile gauze applied. The tape holding the plate in place is not disturbed. The patient is then instructed to keep the toe clean and to change the outer gauze dressing only when needed. If the tape holding the plate is loosened, fresh tape is placed over it without disturbing the plate. It is desirable to leave the plate in place until the nail has grown out to the distal end of its sulcus. However, after 3 weeks the plate may be removed and replaced with ease and without pain. The

Note the relative size of plate and nail. The 60 degree angled corner of this plate projects beyond the soft tissue of the sulcus.

wound by this time has healed and is covered with healthy epithelium. Once the nail has grown out the desired length, the patient is instructed to cut the nail straight across and warned never to trim it back proximally in the sulcus, for this certainly invites the recurrence of the ailment.

If both sides of the same toe are involved, it is advisable to use two small plates. To obtain an accurate fit by use of one plate with both sides turned is too difficult to justify its use.

THE PRODUCTION AND PREVENTION OF THROMBOSIS AND EMBOLISM

EDWARD C. MASON, M.D., Ph.D., and STEARLEY P. HARRISON, M.S., M.D.,
Oklahoma City, Oklahoma

AN experimental study on the subject of the production and prevention of experimental thrombosis and pulmonary embolism was published by one of us (Mason) in 1924 (1). In that report the author included the following data and conclusions: "Intravascular coagulation (thrombosis) was produced by the intravenous administration of the saline extract of dried lung tissue. All injections, in rabbits, were made in the marginal ear vein. It was observed that 1 to 3 minims of the salt extract was sufficient to kill a rabbit in 20 to 30 seconds. Emboli were produced by isolating the external jugular in dogs and occluding the vessel centrally. Tissue extract, generally about 1 cubic centimeter, was injected into the occluded vessel. After about 30 seconds the central occlusion was released and the firm clot (thrombus) was allowed to pass into the circulation."

It was also demonstrated that thrombosis and embolism, resulting from the injection of tissue extract, could be prevented by administering a definite amount of anticoagulant (heparin). By the use of shed blood to standardize the anticoagulant against the coagulant, it was observed that 0.0005 to 0.001 gram of anticoagulant would protect against 0.1 cubic centimeter of lung tissue extract added to the shed blood. "Figuring on this basis the anticoagulant was used for the protection against intravascular coagulation and we found that 0.003 gram of the anticoagulant was always sufficient to protect against 0.3 cubic centimeter of coagulant. Without such protection the rabbits died in 20 to 30 seconds, but, with the protection, the 0.3 cubic centimeter of tissue extract was injected without the least apparent harm to the rabbits." When the anticoagulant was tested on dogs it was found that the administration of 0.001 gram

per pound of body weight was sufficient to change coagulation time from 4 to 10 minutes and such delayed coagulation was maintained for approximately 2 hours. A record of blood pressure and respiration taken during the administration demonstrated no change even when the injection was increased to 0.003 gram per pound of body weight.

The possibility of using heparin to prevent clinical thrombus and embolism was repeatedly emphasized by the author. The following statement was included: "Considering that clinical thrombosis and embolism are, to a certain degree, comparable to experimental thrombosis and embolism, I have suggested that the preparation be put up in 1 cubic centimeter ampules containing 0.100 gram. However, it has been found more satisfactory to put it up in 2 cubic centimeter ampules dissolved in physiological salt solution and sterilized by saturating with boric acid and 0.5 per cent chlorotone." Convinced that heparin as a clinical agent could inhibit intravascular coagulation, the author extended his observations to include human subjects. His results and conclusions are to be found in "A Note on the Use of Heparin in Blood Transfusion" 1924 (2). "Before such clinical application could be made, it was necessary to (1) develop a sterile product, (2) determine the toxicity for the human, (3) determine the dose necessary to give the desired delay in coagulation and (4) the length of duration of its action." These problems were solved and heparin was used in 33 transfusions. Since 1924 volumes have been written on the use of heparin in the prevention of thrombosis and embolism, however the chief contribution has been the production of heparin with greater purity and potency.

EXPERIMENTAL

The following study was undertaken with the desire to analyze and illustrate the mech-

Received for publication May 1, 1925.
of Oklahoma City, Oklahoma.

anism of the production and prevention of thrombosis and embolism

A simple artificial circulatory system was set up (Fig 1), consisting of a Mariot flask (A) as a reservoir, a glass tube equipped with a side arm (B) and a stopcock (C). The entire system was filled with freshly heparinized blood and the side arm packed with a wick through which controlled amounts of tissue extract were added. The blood was continuously circulated through the system for a period of nearly 2 hours, the rate of flow being regulated by the stopcock.

Analysis of the illustrated results demonstrates the following (1) the function of tissue extract in the production of thrombus formation and resulting embolus, (2) the antagonistic action of heparin and tissue extract, (3) the effect of the streaming action of the blood (hemodynamics) on the structure of intravascular clots.

The function of tissue extract in the production of thrombus formation and resulting embolus Thrombus formation is initiated at the base of the side arm where the circulating blood comes in contact with the tissue extract and growth of the thrombus is mainly in the direction of blood flow. Whether or not a clot forms at the point where the tissue extract is introduced depends largely upon the rate of blood flow and also upon the rate at which the tissue extract is introduced. If the rate of

Fig 1 Apparatus for a simple artificial circulatory system

blood flow is slow, allowing the blood to stagnate, the introduction of a small amount of tissue extract will produce a clot, but if the blood volume flow is great the chances for clot formation, at the point of tissue extract administration, may be very slight even though a large amount of tissue extract be introduced.

Frequently during the course of this experiment there may occur a sudden marked slowing or stoppage of circulation due to a portion of the detached thrombus becoming lodged in the bore of the stopcock. The analogy to clinical embolism is thereby demonstrated.

The antagonistic action of heparin and tissue extract The exact mechanism of heparin ac-

Fig 2 Upper surface of longitudinal section of thrombus originally in contact with glass tube, shows result of very rapid coagulation as evidenced by convolutions and eddies related to turbulent flow

Fig 3 Another section which was selected from a region of clot where stream line flow had been established demonstrates the fact that clot is laid down in definite parallel layers

tion, in the prevention of blood coagulation, has been the subject of much research and discussion. The anticoagulant action has been attributed to its being one or more of the following: (1) a powerful antithrombin, (2) an antiprothrombin, and (3) an antithromboplastin. Probably, under selected conditions, heparin may demonstrate each of the three actions, however, the clinical use of heparin, in the prevention and treatment of thrombosis, owes its value to its power to neutralize thromboplastin (tissue extract). In our artificial circulating system we have demonstrated that the anticoagulant action of heparin may be counteracted by the antagonistic action of tissue extract.

Effect of the streaming action of the blood (hemodynamics) on the structure of intravascular clots. Histological examination of an extravascular blood clot, resulting when shed blood is allowed to coagulate in paraffin tubes, reveals a uniform mass of red cells with about the usual number of leucocytes scattered diffusely. There are occasional small, light staining, homogenous areas which suggest collections of platelets and fibrin. In contrast to this, microscopic examination of the intravascular clot reveals an entirely different picture. The intravascular clot usually presents a laminated appearance, some layers being essentially platelets and fibrin alternated with layers of leucocytes and red blood cells enmeshed in fibrin.

The difference in the structure of intravascular and extravascular clots has prompted several observers to conclude that the factors active in intravascular coagulation are quite different from those in extravascular coagulation. We are of the opinion that the principles concerned are the same except for the single mechanical factor of the streaming movement of the blood. The blood passing through the blood vessels encounters resistance due to the friction of moving against the vessels' walls, therefore, the rate of blood flow is different at different points across the diameter of the stream. The external layer of fluid, in contact with the vessel wall, moves very slowly compared with the central portion of the

stream (axial stream). This unequal rate of cross section flow causes an unequal distribution of the formed elements of the blood so that the heaviest (red blood cells) are concentrated in the axial stream and the lighter elements (white blood cells and platelets) are concentrated along the vessel wall. This brings into prominence the preliminary agglutination of platelets and white cell distribution in intravascular coagulation.

Histological preparation of the clot and photomicrographs were made by Professor J. M. Thuringer of the Department of Histology. The clot within the artificial circulatory system was fixed *in situ* and carefully removed, sectioned, and slides prepared for microscopic examination. Figure 2 shows the structure of a longitudinal section of the thrombus taken from the region of the side arm of the apparatus. The upper surface of this section, originally in contact with the glass tube, demonstrates the result of very rapid coagulation as evidenced by the convolutions and eddies related to turbulent flow.

In another section (Fig. 3) selected from a region of the clot where stream line flow had been established, it will be observed that the clot is laid down in definite parallel layers.

CONCLUSIONS

1. Tissue extract is the most potent agent in producing thrombosis and resulting embolism.

2. Whether or not an intravascular clot forms at the point where tissue extract is introduced depends largely upon the rate of blood flow and also upon the rate at which the tissue extract is introduced.

3. The clinical value of heparin in the prevention of thrombosis and embolism is due to its capacity to neutralize thromboplastin (tissue extract).

4. The principles concerned in extravascular coagulation and intravascular coagulation are the same except for the single mechanical factor of the streaming movement of the blood.

FRACTURES OF THE LONG BONES

THE management of fractures of the long bones is as old as surgery itself. Methods of splinting fractures were recorded in the earliest Egyptian writings and in the Bible, and Hippocrates devoted an entire chapter to "Fractures." In those ancient times the principles of immobilization and traction were applied, and were reasonably well understood, and occasionally various rather crude forms of internal fixation were used for the grossly displaced compound fractures of long bones. Only since the latter part of the 19th century, however, when Lister published his monumental work on asepsis and antiseptics, have surgeons been bold enough to treat closed fractures by operative means. During the past 30 or 35 years, fracture management has become a very specialized part of surgery. It is still a fact that the great majority of long bone fractures can be properly treated by manipulation and splinting, or by traction, and some surgeons are content so

long as they can restore length, and maintain reasonably good alignment of the bones. Since Roentgen's discovery of the x-ray, however, many surgeons have striven to restore perfectly the normal anatomy, and, if necessary, by open operation.

As the operative treatment of fractures has advanced materially in the 20th century, so, also, have methods of traction and plaster fixation. Skeletal traction, with the fine Kirschner wire, displaces very little bone, and is most effective when heavy pull is needed, or when the patient's skin will not tolerate adhesive for as long as is necessary to stabilize the fracture. Russell's traction employs the resultant of two forces, thus doubling the amount of pull of the weight applied, and is useful in realigning femoral shaft fractures. Many substitutes for plaster of Paris have been manufactured, but none is as satisfactory for general use by the average surgeon.

The modern operative approach to fracture treatment dates from the work of Lane, of Guy's Hospital in London, about 50 years ago, and from the enthusiasm of Sherman, of Pittsburgh, after World War I. Both of these surgeons advocated early operative reduction of long bone fractures. The metals they used frequently caused reaction of tissues and had to be removed, so that Sherman later abandoned his "vanadium steel," in favor of 18-8 S Mo stainless steel, which, with vitallium, is one of the standard materials used today.

The healing process of a fracture, so well illustrated by a motion picture recently produced by the American College of Surgeons' Committee on Fractures and Other Traumas, begins as soon as the bone is broken, and any delay in treatment postpones healing. There-

fore, the broken bone should be realigned as soon as possible. This is particularly true if open reduction is to be done. The hematoma about the fracture site serves a very definite function, and the less it is disturbed, the better. The earlier the fracture is manipulated, or placed in traction, the easier it is to reduce, and, once open reduction is deemed necessary, the only excuse for delay is an unfavorable condition of the local tissues or of the patient.

The reaction of tissues to metal is no longer a problem, now that 18-8 S Mo stainless steel and vitallium are available. In addition to internal fixation with plates and screws, other forms of metal fixation of long bones have been advocated during the last decade. Prior to World War II the Kuntscher rod became popular in Europe, and was extensively used during the war. It has a place in our armamentarium, but rapidly accumulating experience, particularly in America, seems to indicate that its use should be confined to the femur, and that it may be of very great assistance in stabilizing painful, pathological fractures. External skeletal fixation has lost some of its prewar favor, because of its indiscriminate use by inexperienced surgeons who failed to understand both the fundamental principles of application of the apparatus and of bone healing.

The management of compound fractures received great stimulus during the war, as a result of delayed closure of wounds and the extensive use of antibiotics. The tremendous importance of obtaining a closed wound by means of relaxing incisions, plastic skin flaps, or by skin graft, is being appreciated more and more, not only to prevent draining sinuses and osteomyelitis, but also to speed bone healing, by encouraging revascularization of the osseous fragments.

The vast majority of long bone fractures will heal, if given the opportunity and can, as in the past, be effectively treated by manipu-

lation and splinting, or traction, but without question certain fractures *must be* openly reduced, and secured, while others *can be better* treated by operation than by closed methods. Broadly speaking, the following fractures should be treated by operation: (1) joint fractures, in which there is gross misalignment of articular surfaces, (2) shaft fractures near a joint, where traction or manipulation will not realign the fragments satisfactorily and prevent ultimate deformity of the joint, particularly a weight-bearing joint, (3) fractures with gross interposition of soft tissues, (4) fractures with a large interposed third fragment, holding the main fragments apart, (5) fractures with shortening, which cannot be corrected by traction, (6) fractures of the femoral neck.

Finally the decision to operate upon a fracture depends very much upon the surgeon himself. Does he have the proper tools? Is he operating in the proper surroundings? Does he have adequate assistance? Most important of all, is he qualified by training, experience, and ability to do the operation at hand? If these requisites cannot be fulfilled then the fracture had better be treated by closed methods.

EDWIN F. CAVE

FRACTURES INVOLVING THE HAND, AND THE "POSITION OF FUNCTION"

THE loss of function that so often follows a crushing injury of the hand which is complicated by multiple fractures of carpals, metacarpals and phalanges is too well known to need comment as to its seriousness or importance. Whether because to many men the word "fracture" immediately suggests extension or whether because we have become "pin-and-gadget conscious" one at times cannot escape the impression that we are ignoring basic principles

of fracture treatment and surgical treatment, and thereby vitiating our results

The simple principles of fracture treatment—reduction, immobilization, and immobilization in such a position that there is a minimum of pull on the fractured fragments are as completely applicable to fractures involving the hand as to fractures in any other part of the body. Fortunately, too, the position in which there is a minimum of tension on the fractured fragments almost invariably coincides with the position of function, the position in which the hand is placed if it were to grasp a ball—fingers semiflexed, thumb semiflexed, abducted and facing the fingers, hand in dorsal flexion at the wrist and midway between pronation and supination.

If one simply lets his hand relax on the desk or on the arm of his chair it automatically falls into a position closely resembling the position of function because it is also the position of rest, and one which represents a balance between the muscle pulls exerted upon the bones and joint capsules that make up the framework of the hand. If by contrast one holds his fingers for a few moments in complete extension he quickly realizes that this is not the position of rest but one of tension, and if this position is maintained for a number of weeks with the aid of pins, wires and traction from an extension framework, and if at the same time there is extensive exudation into all the soft tissues not only is it difficult to maintain reduction of fractured fragments but the stiffness that quickly develops at the joints of the hand becomes a serious obstacle to the restoration of function.

The exudation of blood and serum that so quickly infiltrates all the soft tissues after a severe crushing injury suggests another principle of surgical treatment that has been long recognized but again is often ignored—the

principle of applying compression to limit exudation into injured tissues. How important this can be in all types of fracture was strikingly emphasized a few years ago by the late Dr. A. G. Davis and Dr. C. W. Fortune.¹

If one can reduce fractured fragments, immobilize the hand in the position of function and then apply compression to the injured area one is approaching what could be considered the ideal treatment of fractures involving the hand. It was with these principles in mind that Mason and Allen, when confronted with many cases of severe compound injuries of the hand in the Italian Theater of the war, fashioned what they have termed the universal splint, a simple splint hammered out of sheet aluminum and fashioned so as to lie smoothly in the cupped palm of the hand and fingers held in the position of function and over the volar surface of the forearm. By laying the hand with fractured bones reduced upon the splint reduction could be maintained by packing gauze between slightly separated digits, and enveloping gauze covered hand and splint with a compression bandage. Not only was the hand immobilized in the position of function but the much desired compression was secured as well.

After studying the results obtained and reported by Mason and Allen,² in a considerable number of cases one cannot escape the conclusion that they have pointed the way to a greatly improved method of treating fractures of the hand and that pins, intramedullary wires and particularly the so-called banjo splint, except in unusual instances, have little place in the treatment of fractures involving the hand.

IRVIN ABELL
1876-1949

MEMOIRS

DR IRVIN ABELL

THE sudden death of Irvin Abell brought to a close the career of one of the great men of American medicine. The profound grief which followed the announcement of his death and the eulogies of his life and work were evidence of the respect and affection in which he was held by his professional colleagues and by his innumerable friends and patients. Seldom has anyone in any walk of life been accorded the homage given him by the medical profession throughout the entire country, and particularly by the people of Kentucky, the State in which he was born and in which he gained national recognition as a superb surgeon, great administrator and a true humanitarian.

Irvin Abell was known to the profession as a sound clinical surgeon, splendid teacher, and a careful investigator. His logical approach to surgical problems, the clarity of his discussion, the skill with which he performed an operation, and, above all, the consideration he gave to patients and assistants made a visit to his clinic an unforgettable experience. In his desire to know the truth he was a general surgeon in the broadest sense of the term, and by his unusual talents in both the written and spoken word he contributed immeasurably to the part American surgeons played in the dramatic advances of the past fifty years. Because of his extraordinary ability to focus attention on the essentials of any subject, his published works were always instructive. Particularly notable, in the widening horizons of surgery in the early years of this century, were his papers on surgery of the thyroid, the colon, the stomach, duodenum, pancreas, abdominal emergencies and urologic and gynecologic conditions encountered by the general surgeon of his day. In his later years, he turned more often to discussions of the responsibilities of the medical profession to the public, in peace and in war, of medical education, graduate training in surgery, of medicine in industry, and of the influence of pioneers in the profession, particularly in his own state of Kentucky. Scholarly as his writings were, they acquired added luster as he presented them, for he was a most gifted and convincing speaker on every occasion.

As an administrator, Irvin Abell held a unique place in American medicine. In his own medical school at Louisville he organized the surgical teaching, first as Professor of Surgery and later as Clinical Professor, for more than forty years. These responsibilities, together with a busy surgical practice, gave him an insight into problems of teaching and practice which was constantly called upon in the high positions to which he was called in state and national societies and committees. In these activities, his unerring tact, his fairness, and wise counsel were of

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

NEOPLASMS of the intrathoracic part of the esophagus and of the gastric cardia have been among the last to resist surgical attack. Real progress in the development of surgical techniques for the removal of malignant processes involving these organs has been made only in the last 10 years. In *Cancer of the Esophagus and Gastric Cardia*¹ Dr. George Pack has collected the experience and opinions, gained during this period of development, of a number of surgeons who have had an extensive experience with the surgical procedures involved. Among the authors included in this volume, Sweet and Garlock deserve particular credit because they have contributed so much to the development of this field of surgery. This book provides those interested in the surgical management of lesions of the esophagus and cardia a valuable opportunity to review the problems involved in the surgical treatment of these lesions and to compare the techniques and results of operation of a number of different surgeons who have had wide experience in this field.

All the authors of the various papers in this volume give well deserved credit to the progress in anesthesia that has made possible the operative procedures involved in the treatment of carcinoma of the esophagus and gastric cardia. The roentgenologic aspects of the diagnosis of these lesions are well presented. The difficulties in accurate roentgenologic diagnosis of some lesions of the gastric cardia are emphasized. The book includes a splendid chapter on the preoperative and postoperative care of patients who have malignant lesions of the esophagus and cardia. The importance of these measures cannot be overemphasized. It is unfortunate that this volume does not contain a more complete discussion of the endoscopic aspects of lesions of the esophagus and gastric cardia. Esophagoscopy and gastroscopy are indispensable in diagnosing lesions of this region.

It is apparent from a review of the various contributions to the volume that there is still considerable difference of opinion regarding many phases of the operative techniques used in treatment of cancer of the esophagus and gastric cardia. Some of the contributors prefer a preliminary abdominal incision for exploration of lesions of the gastric cardia, others feel that primary transthoracic transdiaphragmatic exploration is to be preferred. Some advocate combined abdominothoracic incisions, others condemn this approach, feeling that a lesion that requires such an incision for its removal probably is inoperable.

anyway. It seems generally agreed that the anastomosis should be accomplished with interrupted silk or cotton sutures throughout. However, there is difference of opinion as to whether the end of the stomach should be closed and the esophagus implanted on its anterior wall or the end of the stomach narrowed and end-to-end anastomosis of the stomach to the esophagus established. Most of the differences in opinion and technique probably are not of fundamental importance. With further experience many of the differences will be resolved.

The mortality rates reported seem reasonable when one considers the age group involved, the physical condition of most patients by the time a diagnosis of the lesion is arrived at, the magnitude of the operation necessary, and the fact that the experience reported covers the period of development of new procedures and techniques. The reported series are not large enough and the condition of the patients involved has not been followed long enough to permit accurate evaluation of prognosis, but the results seem at least to be as good as those which follow operations for carcinoma of the stomach in general.

One cannot read this volume without being impressed by the progress that has been made in this field of surgery during the last decade. Neoplasms of every portion of the esophagus and gastric cardia have become accessible to surgical procedures based on sound principles of surgery for malignant lesions. In this symposium Dr. Pack has brought together, from many sources, a wealth of experiences covering almost all phases of the problems involved in the surgical treatment of carcinoma of the esophagus and gastric cardia. It is a worth-while addition to medical literature.

O. T. CLAGETT

THE volume *The Normal and Pathological Physiology of Pregnancy*² is a collection of papers given at a conference of the Committee on Human Reproduction of the National Research Council, January 30 and 31, 1948. The various articles are well written and are of particular interest for obstetricians and those doing research in obstetrics. For the benefit of those who may wish to secure the volume, a brief summary of some of the articles is appended.

In addition to its functions as an organ subserving the catabolic and anabolic growth requirements of

¹THE NORMAL AND PATHOLOGICAL PHYSIOLOGY OF PREGNANCY. Proceedings of the Conference of the Committee on Human Reproduction of the National Research Council on behalf of the National Committee on Maternal Health held in New York City, January, 1948. Reprinted from *Obstetrical and Gynecological Survey*, Vol. 3, No. 5, October 1948. Baltimore: The Williams & Wilkins Co., 1948.

¹CANCER OF THE ESOPHAGUS AND GASTRIC CARDIA. Edited by George T. Pack, B. S., M. D. St. Louis: The C. V. Mosby Co., 1949.

the fetus, the placenta is an endocrine organ which appears to synthesize and secrete several hormones. During toxemia, there are definite objective evidences for dysfunction of the placenta, in regard to the elaboration of both enzymes and hormones, and its capacities for transmission. Such dysfunction appears to be associated with and probably caused by the diffuse trophoblast injury.

Dilation of the cervix is associated with a gradient of diminishing physiological activity from the fundus to the lower uterine segment. Deviation from this pattern is associated with prolongation of labor or prevention of dilation. The physiological basis of this gradient of activity is discussed with respect to the tissue tensions in fundus and lower uterine segment respectively, in the fundus the tension exceeds that in the cervix by about 3 r.

The precipitable iodine of the serum rises sharply at the onset of pregnancy from the normal concentration of 4 to 8 γ per cent to concentrations between 6 and 10 γ per cent, and remains at these levels until delivery, after which it rapidly returns to the normal range. No evidence has been found in a limited number of observations that serum precipitable iodine is abnormal in women with infertility or suffering from toxemias of pregnancy.

The study of the excretion of urinary metabolites of the ovarian, placental, and adrenal hormones has thrown considerable light on the interrelationship of the various endocrine glands in pregnancy.

EDWARD L. CORNELL

THE fourth edition of Doctor Partipilo's book¹ on surgical technique represents a complete revision of his previous fine textbook. In his preface the author states that "endeavor has been made to include in each chapter a review of surgical anatomy and a discussion of pertinent pathologic, physiologic, and clinical aspects of each subject. Complete chapters were devoted to consideration of the physiologic basis for the treatment of peptic ulcers, duodenal obstruction, intestinal obstruction, peritonitis, diseases of the gall bladder and extrahepatic bile ducts, diseases of the pancreas, thoracic diseases, diseases of the peripheral vascular system, and diseases of the colon and rectum."

The general principles of operative surgery are discussed in an interesting manner, and the technical steps of each operative procedure are described in detail and are illustrated by exceptionally fine line drawings by W. C. Shepard and Hooker Goodwin. There are 547 figures containing 997 illustrations accompanying the text. Each chapter ends with a brief bibliography and a list of questions for the student.

In a book of this scope and size, there is, it seems to me, too much space devoted to a procedure which has the limited application that gastrostomy has and a disproportionately large emphasis on duo-

denal obstruction. The book as a whole would have gained had those chapters been reduced for the more complete presentation of surgical principles in thoracic disease, but it is a book that can be recommended highly to the medical student, surgical resident, and general surgeon.

W. D. SEYBOLD

IN Dr. Quiring's *Collateral Circulation*,² there is presented an unusually convenient and concise account of the major arterial and venous channels, which offer possible bypaths for the circulation in cases of occlusion.

With excellent selective judgment, the author has taken examples from an abundant literature and has arranged them on a regional basis, he has portrayed, in 61 simple, diagrammatic figures, the circuitous routes by which blood passes through the newly enlarged, initially subsidiary, channels.

Following an introductory review of the embryonic, or primordial, capillary beds from which adult arteries and veins are selectively derived, Dr. Quiring discusses, in succession, the dynamics and associated features of collateral connections, chief vascular patterns, and the anastomoses which occur in the head, neck, trunk, heart, and extremities. Each complex region is exhaustively handled, to offer details of circulatory anatomy, for example, the orbit, the eyelids, the tonsils, the suprarenal glands and kidneys, the cardiac wall, the ear and temporal bone, the uterus and vagina, are treated from the standpoints of vascular requirement and pleomorphic source.

Dr. Quiring corrects the fallacious notion held by many modern writers, that all important anatomic and medicosurgical knowledge is a possession of recent acquisition; he pays tribute to the important contributions of Aristotle, Celsus, Galen, Vesalius, Paré, Harvey, and Hunter, their observations are placed appropriately with those of recent times.

The volume closes with a useful bibliography of almost 100 items. Altogether, this small book of 142 pages will be a most serviceable addition to the practitioner's library. It will also be an illuminating element among the textbooks assignable for students' use in the medical courses, being a dependable summary of many separate treatises, it presents fundamental information to the beginner at the time when correlation between current laboratory observation and prospective practice is most effectively established.

BARRY ANSON

THE book *Clinical Aspects and Treatment of Surgical Infections*,³ a companion volume to his *Treatise on Surgical Infections*, deals in the broadest fashion with infections as seen by the surgeon. The management of surgical infections is not simply a

²COLLATERAL CIRCULATION (ANATOMICAL ASPECTS) By Daniel P. Quiring, Ph.D. Illustrated by Margaret Holman, Anatomy Division, Cleveland Clinic Foundation. Philadelphia: Lea & Febiger, 1949.

³CLINICAL ASPECTS AND TREATMENT OF SURGICAL INFECTIONS. By Frank Lamont Melency, M.D., F.A.C.S. Foreword by Allen O. Whipple, M.D. Philadelphia and London: W. B. Saunders Co., 1949.

¹SURGICAL TECHNIQUE AND PRINCIPLES OF OPERATIVE SURGERY. By A. V. Partipilo, M.D., F.A.C.S. Foreword by Alton Ochsner, M.D., F.A.C.S. 4th rev. ed. Philadelphia: Lea & Febiger, 1949.

matter of administering the proper chemotherapeutic or antibiotic drugs. Under many circumstances these drugs are of no value. In the majority of instances the drugs are simply adjuvants to other surgical measures, while in but few cases will drugs alone suffice. This broad concept of the surgical infection places the book at once among the classics in surgery. While the search for specific drugs and other specific agents does not cease and the rewards have been high, Dr. Meleney recognizes the fact that the surgeon cannot depend on drugs alone in his fight against infection. The surgeon is interested not only in the causative organism but also in those other factors which lead to the development of infections. He realizes that bacteria alone do not necessarily lead to infection. Bacteria are often simply fortuitous occupants of tissues or organs, and their growth and elaboration of toxins but a complication of some underlying pathologic process. The surgeon who would deal intelligently with these surgical entities or complications must be able to assess the significance of the various elements which enter into them.

Following an introductory chapter on the physiologic aspects of surgical infections by John S. Lockwood, Dr. Meleney covers the whole field of surgery by systems and regions. Each entity is first discussed from the standpoint of pathogenesis, upon which obviously logical therapy is based. Following adequate presentation of pathogenesis there follow bacteriologic observations and symptoms, signs, and treatment. Each part separately and the whole are presented with the thoroughness of a textbook of surgery, so that the student as well as the practicing surgeon is given a complete picture. Each section is followed by illustrative cases to bring out certain elements in signs, symptoms, or care, and each case is succinctly epitomized.

It would be difficult to select one chapter as more thoroughly presented than another. Meleney is perhaps best known for his pioneer contribution in bacterial synergistic gangrene, and although the chapter dealing with infections of the skin and subcutaneous tissues which contains the discussion of this entity is most excellent, all other chapters are equally thorough. One could scarcely find anywhere an equal to the chapter on appendicitis.

The chapter on peritonitis has been contributed by Harold D. Harvey, and a final chapter on war wounds has been prepared by Alfred B. Longacre and William R. Sandusky.

The book will be invaluable to both student and practitioner, and its comprehensive presentation and extensive bibliographic references will recommend it to the teacher.

MICHAEL L. MASON

THE book *Neurovegetativo*¹ is an accumulation of general information concerning the physiology and therapeutics of the neurovegetative system. It is a result of 20 years experience and study in various European universities.

¹NEUROVEGETATIVO. By Estanislao Lluerna Uranga. Buenos Aires, Argentina. Lopez & Etchegoyen, 1948.

It is most comprehensive and is divided into 6 parts, the true perspective of the vegetative system, the extrinsic constants, diagnostic neurovegetative methods, the vegetative pathology, therapeutics and operative techniques. It is a practical book and appears to be designed to contain all the general subjects of medicine with a neurologist's and neurosurgeon's background.

The author presents his observations in temperamental vegetativism and neurovegetative effects in stomach ulcers, in appendicitis, in cancer, the emotional and psychovegetation response in trauma whether psychic or somatic, the neurovegetative attitude in relation to surgical prognosis. He narrates the results of his experimental studies concerning the physiopathology of peripheral vascular diseases, plethysmographic tracings, the vascular nutrition of the myocardium, the electric excitation of the vagi in the neck, stimulation provoked by ergotoxins and the physiopathology of the sinocarotid reflex.

The book has an exceptional comprehensive bibliography and is generously illustrated with excellent clear cuts. The last chapter on technique is most worth while from a practical viewpoint. It presents various surgical procedures illustrated in drawings so lucid that a beginner in neurosurgery may follow them with a high degree of confidence. This latter part of the volume is by far the outstanding feature and redeems whatever shortcomings and controversial issues which may be found in the preceding 5 chapters. The approach of the work is entirely different from anything found in the English literature and again for this reason the book is a valued addition to the neurosurgeon's library.

STEPHEN A. ZIEMAN

IN presenting his new text, *Obstetric Analgesia and Anesthesia*,² Dr. Snyder's objective is to consider the problem of obstetric pain relief from the fundamental physiologic point of view. He is primarily interested in the effect of pain relieving drugs on the fetus and on the mechanism of labor, and in determining these effects accurately and experimentally. Thus, the entire first section of this book (more than half the text) is devoted to a review of these basic aspects of the problem—fetal respiration, asphyxia and atelectasis, and a laboratory method for assaying the effects of various agents on the fetus and on the labor, etc. And in the consideration of the individual drugs available, which occupies the second and somewhat shorter section of the book, the presentation continually stresses the impact of each agent on the physiology of the fetus and on the course of labor equally with its pharmacologic action in effecting pain relief.

That this is a worthy objective is above dispute. A constant reconsideration of the fundamental physiology involved (in contrast to "Clinical Evaluations") is not only the better approach to medical

²OBSTETRIC ANALGESIA AND ANESTHESIA, THEIR EFFECTS UPON LABOR AND THE CHILD. By Franklin F. Snyder, M.D. Philadelphia and London: W. B. Saunders Co., 1949.

problems in general, it is imperative in the field of obstetric pain relief. Two patients of remarkably different environment—the mother and the baby—share each medication, and it is essential to know as accurately as possible the physiology of each of these patients and how it may be modified by the pharmacologic action of the administered drug.

The extent to which Dr Snyder achieves this objective, however, varies. Certainly it is true that his compendium of information on intrauterine fetal respiratory efforts, on the establishment of initial respirations and on neonatal asphyxia and atelectasis is one of the most complete at present available in medical literature. His own work of the past 2 decades and the observations of others on these and related fields are here gathered together in readily accessible form.

However, it must also be pointed out that in expressing his views with vigor and cogency, the author's emphasis is sometimes partisan. Consider, for example, the total effect of the following 2 sentences: "How frequently the effects of asphyxia at birth are manifest in later life as mental retardation or brain lesions is difficult to prove. In 70 per cent of a group of 900 children in whom brain lesions were evident, Schreiber obtained a history of asphyxia at the time of birth." Each of these sentences is true, yet the impact of the paragraph on the reader is quite different than it would have been had the author, in his second sentence, quoted the work of McPhail and Hall (1941), for example, rather than selecting Schreiber's work. The true fact selected for presentation weights the final effect by its emphasis.

Also under the heading of emphasis it should be noted that morphine and scopolamine, alone or in combination, occupy 55 pages of text, while low spinal and continuous spinal anesthesia are covered in 5½ pages. Rectal ether, magnesium sulfate, and avertin and paraldehyde receive 24 pages and chloroform has a 12 page chapter, on the other hand, all caudal anesthesia, both continuous and intermittent, is covered in 14 pages. This distribution of text reflects to a great extent the author's interest and own experimental work more than it indicates the frequency of use of these forms of analgesia or anesthesia in practice.

Nevertheless, as a source book of fundamental information on fetal and neonatal respirations—normally and as influenced by drugs—this book has a definite place. The author has appended an excellent summary to each chapter which considerably enhances the book's value. ALLAN C BARNES

DURING the recent World War II considerable momentum was given to the development of civilian blood banks as a measure for national defense. Prior to this time transfusion services had evolved by trial and error methods, the medical literature containing the experiences of many individuals along these lines. To facilitate expansion of blood transfusion facilities during those busy days the office of civilian defense authorized the publication of a

manual or handbook on organization and operation of such a hospital service. Because certain inadequacies were present in this working outline and due to the crystallization of further experiences in the field, the coauthors (E. L. D. and J. A. B.) collaborated with a third (R. C. H.) to produce the present comprehensive volume *Blood Transfusion*.¹ They have chosen to cover the entire field of blood transfusion rather than to limit themselves to either whole blood or any of its fractions, although obvious emphasis has been given to whole blood.

The text is written not only for the medical student and physician but also for the laboratory technician upon whose shoulders falls a considerable responsibility for successful blood bank operation. The scope and contents can best be appreciated by an outline of the 9 major sections which consists of (1) historical perspective, (2) clinical usage, (3) immunology of blood, (4) technical section, (5) transfusion of whole blood, (6) preparation and administration of plasma, (7) blood derivatives and plasma substitutes, (8) operation of hospital blood bank, (9) transfusion apparatus.

While the titles speak for themselves, the technical section should be given some special comment. It is well organized and sufficiently clear for handy reference. In many instances the procedures have been illustrated in such a way that the margins of the page constitute a series of flow diagrams. The authors have added the important factor of visual aid in obtaining clarity of sequence in the laboratory testing. This will be appreciated by the technician or house officer who is learning the procedure for the first time. Each section ends with a liberal though not cumbersome bibliography. It is appreciated that many hundreds of papers have filtered into the literature on various aspects of blood transfusion, some of which contain time tested information. These have been appended and add to the value of the chapters.

In criticism one feels that the volume contains some degree of repetition. This may be unavoidable due to the complete consideration of the various blood fractions according to a similar outline of inquiry. This, of course, makes each section sufficiently complete to obviate the need for further cross reference in using the text as a source book. Although the authors have stated their fear that any first edition will usually fail to include some unrecorded worth-while information, the book seems to be quite complete. In addition, the authors have reported their own extensive experience in a clear manner. The volume should be of definite practical value. WALTER W. CARROLL

THE work, *Diseases of the Nose and Throat, a Textbook for Students and Practitioners*² originally

¹BLOOD TRANSFUSION. By Elmer L. DeGowin M.D., Robert C. Hardin M.D. and John B. Alsever, M.D. Philadelphia and London W. B. Saunders Co., 1949.

²DISEASES OF THE NOSE AND THROAT, A TEXTBOOK FOR STUDENTS AND PRACTITIONERS. By Sir St. Clair Thomson M.D., and V. E. Negus, M.S. 5th ed. New York: Appleton Century Crofts, Inc. 1949.

REVIEWS OF NEW BOOKS

published by Britain's leading rhinolaryngologist in 1911, was at his request completely revised by Mr Negus in 1937 in order, as Sir St Clair stated, that it "should not fail in modernity."

Many of the old figures have been discarded, and the new plates, especially color pictures of laryngeal and esophageal conditions, are brilliantly accurate. The text is carefully subdivided and thoroughly indexed, and references to authors, especially American, follow each chapter.

Mr Negus has rewritten the chapters on malignancies of the nasopharynx and larynx, on treatment by sulfonamides and penicillin, radiotherapy and vitamins, on allergy, and on nasal physiology. Operative procedures are detailed in the appropriate sections, including peroral endoscopy. A section on inflammatory diseases of the lung has been added, and excellent discussion of the diagnosis and management of bronchogenic malignancy is given.

A formulary based on the British pharmacopeia follows the text. This is a complete and thorough work of reference for the specialist in rhinology and laryngology, and a most valuable aid for beginners in this complicated and difficult field, it reflects great credit on the present editor, who is an internationally acknowledged authority.

RALPH A. FENTON

THE volume *The Venereal Diseases, a Manual for Practitioners and Students*¹ is well written, informative, and is very easily read. Male and female gonorrhea with its complications are discussed in detail. Sulfonamide therapy is recommended as the treatment of choice in gonorrhea. In cases of failure of treatment, the administration of another sulfonamide is advised. Local irrigations, in addition, are recommended as an adjuvant in treatment. A chapter on penicillin has been added.

Nonspecific urethritis, prostaticitis, and seminal vesiculitis are carefully reviewed. The importance of male and female trichomoniasis is pointed out. Mild anterior urethral strictures causing urethral discharge or a "morning drop" are seemingly uncommon in Britain. The discussion of acute and chronic prostaticitis and abscess formation is adequate. The routine practice of irrigating the urethra before Reiter's static cultures are taken could be deleted. Reiter's syndrome is well presented but consideration of brilliant cures with intravenous arsenicals has been omitted.

The chapter on syphilis is excellent and complete. Excellent photographs, some in color, have been added. The outlines and suggestions on syphilis therapy are sane and practical. The combined penicillin arsenic-bismuth therapy is strongly recommended.

Chancroids, lymphogranuloma venereum, and granuloma inguinale are mentioned. The potential value of streptomycin in the treatment of some venereal diseases might well have been mentioned.

¹THE VENEREAL DISEASES, A MANUAL FOR PRACTITIONERS AND STUDENTS. By James Marshall, M.D. B.S., M.P.C.S. L.R.C.P. 2d ed. London: Macmillan & Co. Ltd. 1948.

This volume is a useful reference book in the diagnostic and therapeutic field of venereal diseases. With all the recent social legislation, the author laments the fact that compulsory premarital examination laws have not been enacted in the British Isles.

LEANDER W. RIBA

THE latest volume on diabetes, *Diabetes and its Treatment*,² designed to give the general practitioner a clinical approach to an understanding of the disease and its treatment, is a comprehensive, well written work. The general discussions, as might be expected from a writer who is one of the foremost clinicians especially interested in diabetes, are excellent. This is one of the best available books on the subject. A particular attempt is made to simplify the fundamental, yet often difficult, problem of diet by providing a special section or system of diets, which may be obtained separately by the patient. This section contains no less than 317 diets and daily menus adapted to men and women of varying build, providing 25, 27.5, and 30 calories per kilogram daily as may be needed to maintain their optimal weights, included also are maintenance diets for children. By means of tables the physician can select the diet he believes appropriate for the individual patient who, given the number of the diet, is able to find it in a special book of diets furnished him. This method of prescribing diets is practical, efficient, and time-saving, and of particular value if the services of a dietitian are not available, it obviously requires that the doctor and his patients possess the author's list of diets and menus.

WALTER H. NADLER

IN the words of the authors "the central purpose of this treatise is to present the pharmacodynamic and pharmacotherapeutic actions of drugs as they are used in the treatment and cure of disease. The principal emphasis of drug action has been the clinical application, as the text is intended mainly for medical students and the physicians who must use and evaluate drugs in the treatment of the sick." *Pharmacological Principles of Medical Practice*³ is a medium sized treatise (963 pages) with 94 figures and 72 tables, and written to a considerable extent in the lecturer's style. Considerable attention is given to the historical evolution of pharmacology as a scientific discipline and the book contains 24 portraits of individuals who have made outstanding contributions to pharmacology and therapeutics. The general content is essentially similar to that of other texts in this field although there is some variation from type in the organization of the material. The latter is brought up to date by inclusion of the many drugs of recent interest. The quality of the treatment of subject matter is somewhat uneven, being particularly good in the field of the general anesthetics and vascular agents, but less so in some anesthetic and its treatment. By Joseph H. Barach, M.D. F.A.C.P. New York: Oxford University Press, 1949.

³PHARMACOLOGIC PRINCIPLES OF MEDICAL PRACTICE. By John C. Krantz, Jr. and C. Jelleff Carr. Baltimore: The Williams & Wilkins Co., 1949.

of the other fields. On the whole it seems well suited to the audience to which it is directed.

CARL A. DRAGSTEDT

ALMOST a half century has passed since *Human Embryology and Morphology*¹ first took its place among the more pretentious textbooks on human development. Revised and somewhat enlarged, both in descriptions and illustrations, it now reappears as a sixth edition under the same authorship and finds itself competing with no book of equal age and some that comparatively are veritable infants.

Age, in this instance, does not imply obsolescence. This book has always had distinctive qualities that endear it to old friends and appeal to new readers who are broad in background. Rarely does one encounter a text in this or allied fields that makes serious reading so pleasant and profitable a task. Outside of a gifted style in description and exposition, the author has become notable for his insistence on interpreting the events of development in the light of evolution. The continuous correlations with conditions existing in lower vertebrates is a delight even when it verges on the speculative. It contrasts sharply with some modern embryologies that never offer a hint that man shares anything developmentally with other vertebrates, or even with other mammals, and with equal success conceal even those features that are peculiarly anthropoid.

All the praise that is due Sir Arthur does not imply that his book is beyond criticism. Early development is slighted in many regards in contrast to the plenary treatment of the morphogenesis of particular organs, systems, and parts. The illustrations continue to be simple pen drawings, printed on unglazed paper. A few are badly drawn and some others should be replaced with figures based on more typical stages or authentic material, but on the whole the illustrations are more effective than their unambitious style would lead one to expect. The order of treatment is partly regional, partly by organ systems, and not at all by germ layers. This has both advantages and disadvantages, the clarity attained is far better than in some British texts which have adhered strictly to a regional treatment.

Descending to specific details concerning this sixth edition, one finds that the number of chapters has increased from 30 to 32, the number of figures from 535 to 578 and the number of pages from 558 to 690. The valuable "Notes and References" at the end of each chapter have been expanded with citations to recent literature and continue to be enlivened with personal comment. The author states that hardly a page of the text has escaped some degree of amendment, and in his preface he documents some of these alterations. Despite such commendable improvements, this book in its current dress will impress old readers as not greatly changed, either in plan or in substance.

L. B. AREY

¹HUMAN EMBRYOLOGY AND MORPHOLOGY. By Sir Arthur Keith. (3th rev. ed.) Baltimore: The Williams & Wilkins Co. 1915.

THE atlas of 101 colored illustrations, *The Color Collection of Medical Illustrations*² portrays the anatomy and many of the common pathological conditions found in the lungs and heart, the gastrointestinal tract, the male reproductive organs, and the breast. Accompanying many of the illustrations are reproductions of pertinent roentgenograms, and on each page a discussion of the anatomy, of the pathological changes portrayed, of the course of the disease, and brief comments on symptomatology and diagnosis accompany the colored illustration. The textual material has been prepared by a number of distinguished medical men but the text does not indicate the specific contribution of each of the men.

This volume will be of particular value to medical students in helping them to review anatomical studies and to visualize pathological conditions which they are meeting for the first time. It should be of real assistance to teachers in presenting to students accurate and beautiful illustrations of conditions which the student has not yet had the opportunity to see in the laboratory or operating room. It can be of great help to the young surgeon in refreshing his anatomical knowledge and in enlarging his mental concepts of the pathological changes that occur in the viscera depicted.

SUMNER I. KOCH

THE book *Nursing Care of Neurosurgical Patients*³ a composite of lectures by the author, is based on years of personal experience in the care of neurosurgical patients. It presents the nursing situations particularly concerned with these patients.

Following a brief review of the essential anatomy, the author discusses clinical signs and symptoms indicative of intracranial pressure. The treatment—both preoperative preparation and postoperative care—and rehabilitation programs peculiar to the neurosurgical patient are clearly and simply presented. Special mention is made of traumatic head injuries, spinal cord tumors, neuralgias, and procedures applicable to neurosurgery, including among others sympathectomy, peripheral nerve surgery, and spinal puncture. The importance of the ability and co-operation of the neurosurgical team in the operating room is emphasized as the author describes a typical craniotomy.

Excellent diagrams throughout the book, including those of surgical setups and special operative instruments, help the reader to utilize the text to the greatest advantage. Pertinent detailed nursing procedures are given in the appendix. The value of the book lies not only in its presentation of basic nursing principles, but also as a reference in neurosurgical surgery. The information in this book should

²THE COLOR COLLECTION OF MEDICAL ILLUSTRATIONS. A COMPILATION OF PATHOLOGICAL AND ANATOMICAL PICTURES. By Frank H. Netter, M.D. Summit, New Jersey: Ciba Pharmaceutical Products, Inc. 1945.

³NURSING CARE OF NEUROSURGICAL PATIENTS. By Polina M. Klemme, M.D., F.I.C.S., F.A.C.S. Springfield, Illinois: Charles C. Thomas, 1949.

REVIEWS OF NEW BOOKS

be invaluable to the nurse caring for neurosurgical patients
KATHERINE T SMITH.

THE eighty-six page monograph *Posttraumatic Epilepsy*¹ is one of a series of treatises in the neurosurgery division of "American Lectures in Surgery." The author needs no introduction to neurologists in this country or abroad, and he has in this tidy and timely work presented in a simple, direct manner pertinent, up to date information concerning a subject of much importance to many doctors and patients alike. The book is shorn of all unnecessary discussion, and presentation of the subject material is in a modest but entirely adequate manner.

The pathogenesis of posttraumatic epilepsy is clearly and simply demonstrated, and such practical material as the location of the lesion, the extent of cortical involvement, and cerebrovascular instability are discussed in their importance to the symptomatology.

There is an excellent chapter on electroencephalographic manifestations of posttraumatic epilepsy, and surgical procedures are well covered. Apparently the surgical concepts have been written based upon the author's own wide experience. It is reassuring to find that Dr Walker is conservative in his attitude toward cranioplasty and that undue enthusiasm does not get the better of his sound surgical judgment. There are many good illustrations.

The author has stressed the importance of the counseling of not only patients but relatives as well in the presence of this type of epilepsy, and he points out the necessity of overcoming in the patient's mind the false stigmas which are so unwisely attached in the mind of the laity to the general subject of epilepsy.

This is an excellent book. The author has accomplished in a few pages what previously has, in some instances, required large volumes.
JOHN MARTIN

AN excellent book written by the Drs Boas² for a study by medical students and general practitioners. The presentation of the clinical pictures of angina pectoris and myocardial infarction is well done. The description of the sequence of events which may happen to the patient with angina pectoris is particularly graphic. The importance of a good history correlated with physical examination and laboratory procedures is stressed.

The sections on embryology, anatomy, and electrocardiography are rather brief.

The authors have been rather dogmatic about some of the controversial points covered, such as the value of certain drugs in cardiac therapy and the relationship of trauma or strain to coronary thrombosis. Many authorities do not believe that trauma

¹POSTTRAUMATIC EPILEPSY. By A. Earl Walker M D. Springfield Illinois Charles C Thomas 1949.
²CORONARY ARTERY DISEASE. By Ernst P Boas M D and Norman F Boas M D. Chicago The Year Book Publishers Inc. 1949.

or sudden stress are a cause of coronary thrombosis as the authors suggest
CHAUNCEY MAHER.

THE book *Operative Surgery*³ is a one volume work containing detailed descriptions of the majority of the standard operations of general surgery. The author has attempted to include only material of practical value, and no effort has been made to cover indications for surgery, preoperative diagnosis, or anesthesia. Discussions of surgical pathology, apart from descriptions of the gross appearance of abnormal conditions as seen at the operating table, have been omitted purposely. The bulk of the volume is devoted to abdominal surgery, but there are also chapters on surgery of the skin, mouth, salivary glands, neck, chest and mediastinum, genitourinary system, blood vessels, bones and joints, and the extremities. In addition, chapters on preoperative preparation and postoperative care and a general chapter on instruments, positioning of patients, sutures and knot tying, and other miscellaneous topics, have been included. In general, the technical aspects of the operations included are covered in considerable and adequate detail. The binding, typography, and paper are pleasing and the book has been kept to the reasonable size, including the index, of 698 pages. All the illustrations are new and an adequate number have been included.

The book was written particularly for the younger man in surgery and for house officers. As the author points out in the preface, while there can be no substitute for training and experience, there are principles that can be passed along by the mature surgeon. The method of presentation is somewhat unusual and not displeasing. In each section the more important surgical lesions of the organ or anatomic area being discussed are described briefly. The associated conditions that might be encountered are listed and the bulk of each section is then devoted to detailed descriptions of the operations used to treat the condition in question. In each section there is a short discussion of the preoperative preparation and taining to the particular organ or operation, and a description of pertinent postoperative care is added.

All references to current periodic literature and virtually all other references have been purposely omitted, as have critical evaluations of the various operations, in most cases. These omissions, along with the author's failure to comment on the hazards and pitfalls of the operations in question, as well as a seemingly studied effort to exclude controversial discussion, leave one with the impression that the technical side of general surgery is without problems or complications and that the field is almost entirely static. In the hands of the less mature surgeon, particularly one with limited training whose knowledge of surgical literature may be limited, the omissions may be serious. However, the author usually indicates his procedure of choice when several operations

³OPERATIVE SURGERY. By Frederick C Hill, B.A., M S (Surg.), M D. Foreword by Charles W Mayo, B.A., M S (Surg.), M.D. New York Oxford University Press, 1949.

are listed, so that the reader is not entirely without critical guidance. Obviously, also, in the effort to cover the field in a single volume, the author was forced largely to exclude all ancillary material.

The value of such books as *Operative Surgery* cannot be questioned. The gap in surgical writing between the usual textbook of surgery, designed essentially for students, and surgical monographs and the periodic literature prepared by and for mature

surgical specialists, has been great. The usual text book devotes little space to technical considerations, while the assumption is generally made in surgical monographs that most technical aspects are familiar to the reader. Hill's volume fits well into this gap, and, when it is used in conjunction with standard texts and surgical journals, should prove of real value in supplying part of the essential background of a surgeon.

B MARDEN BLACK.

COLLECTIVE REVIEW

INTERNAL STRANGULATING OBSTRUCTION OF THE BOWEL

ROBERT T CROWLEY, M D, F A C S, and JAMES M WINFIELD, M D, F A C S,
New York, New York

FEW more positive indications for surgical intervention exist than intestinal obstruction in which there is a coexistent embarrassment of the blood supply to the obstructed bowel segment. Such obstructions are generally termed as strangulating obstructions and differentiate them from intestinal obstruction of the simple type in which the bowel is obstructed but without any coexistent major impairment of the intestinal blood supply.

Strangulating bowel obstruction is further classified into two types (1) external, in which the cause of the obstruction and the concurrent impairment of the blood supply are apparent by demonstrable external signs, e g, an irreducible mass through an abdominal orifice, and (2) internal, in which the signs of obstruction and circulatory embarrassment is completely concealed within the abdominal parietes. In strangulating obstructions of the external type, little diagnostic difficulty is usually presented, but when the obstruction is of the nature of an internal strangulating lesion, the problem of diagnosis preoperatively may be considerable and errors frequent. The subsequent observations are based upon this latter type of strangulating obstruction.

Errors in the diagnosis of strangulating internal obstruction arise from several sources

- 1 The cause of the obstruction is concealed
- 2 There is no single pathognomonic sign by which the presence of a strangulating internal obstruction can be absolutely identified
- 3 There is a large number of acute surgical lesions of the abdomen with which the condition may be confused

The diagnosis of the condition of internal strangulating obstruction rests, therefore, upon the recognition and evaluation of all of the features presented. It is the belief of the writers that strangulating internal obstruction can, in the great majority of instances, be diagnosed preoperatively if the available diagnostic criteria incident to the lesion are carefully searched for and interpreted. The following features concerned in the diagnosis are presented by the writers in the hope that they may prove of some value to others in the preoperative recognition of the condition.

GENERAL CONSIDERATIONS IN PREOPERATIVE DIAGNOSIS

Intestinal obstruction in general has been elsewhere defined as a condition in which there exists, from whatever cause, a cessation, either partial or complete, of the normal forward motion of the intestinal content for a period long enough to produce local and general pathological changes (8).

Internal strangulating obstruction, as the term is to be employed here, denotes a condition of obstruction arising from causes not apparent from external examination of the abdomen, in which

From the Department of Surgery, New York Medical College and the Flower Fifth Avenue Hospitals, New York, New York and the Department of Surgery, Wayne University College of Medicine and Receiving Hospital, Detroit, Michigan

there is a coexistent impairment of the mesenteric blood supply to the obstructed bowel segment

The local and general pathological alterations occurring in strangulating internal obstruction arise mainly from two features

1 A cessation of the normal forward motion of the bowel content, from whatever cause, (distention effect)

2 An interference with the mesenteric blood supply to the obstructed bowel segment (circulatory effect)

Distention effects The importance of the distention factor in intestinal obstruction of any type is well recognized and has been appropriately stressed in the experimental and clinical literature dealing with the subject, and little reiteration need be made here beyond recalling the essential changes by which distention effects are produced (11, 17, 18, 21, 42)

Whenever the normal forward motion of the bowel content is impaired, from whatever cause, distention of the bowel results from the accumulation of gas and fluid in the obstructed bowel segment. This accumulation produces an increasing intraluminal pressure within the obstructed bowel segment and in the normal bowel above, which serves as a stimulus for the outpouring of the fluid and chloride content of the blood into the bowel. A decrease in the circulating blood volume with consequent dehydration and hemoconcentration thereby occurs which progresses with the distention. If the distention is unrelieved and the depleted fluid and chloride lost from the effective circulation are not replaced, death as a result of the distention factor alone may occur. The urea and fibrinogen levels of the blood are also elevated as a result of the distention.

Besides causing the dehydration and hemoconcentration effect, distention is a prime factor in the production of pain associated with obstruction (2). The bowel is generally insensitive to the ordinary pain-producing stimuli such as cutting, burning, pinching, but under excessive degrees of increased intraluminal pressure produced by distention, pain is invariably present. The pain incident to distention is of a rather characteristic type. It is generally cramplike in nature, undergoing exacerbations periodically with peristalsis. Its intensity is roughly proportional to the amount of distention. It is only diffusely localized in the abdomen, the sensation being felt in the upper area of the abdomen when the proximal segments of the bowel are involved, and in the lower abdominal areas when the obstructive lesion is in the more distal portions of the intestine. When the distention stimulus is decreased or re-

moved by decompression, the pain diminishes or disappears accordingly.

Obstruction distention is also responsible for certain effects (reflex), the exact nature of which are still obscure. Changes in the blood pressure and respiration have been noted experimentally when the various parts of the bowel have been subjected to high degrees of distention (8, 36). The reflex character of these changes has been demonstrated by their abolition by removal or inactivation of the afferent nervous pathways (visceral afferents) which are stimulated by excessive degrees of intraluminal pressure. Perhaps the most significant features of these reflex effects concerned with the distention factor is vomiting which occurs early in certain obstructive cases. It is probable that such vomiting is in part reflex in origin, resulting from stimulation of the splanchnic visceral afferents from the bowel by the increased intraluminal pressure incident to the distention.

While the most significant changes in the circulation to the bowel are produced by lesions involving the vascular radicals of the mesentery, the pressure of distention, if present in a considerable degree, will result in marked alterations in the intraluminal circulation in the distended bowel segment, as evidenced grossly by stasis, venous engorgement, and edema (24, 39).

A schematic summary of the effects of distention just discussed is given below (9).

Specific causal agent producing obstruction—

Stasis of intestinal content—

Distention of intestinal lumen—

Dechlorination—dehydration—elevation of urea and fibrinogen blood levels—hollow viscus pain

Vomiting—change in respiration—blood pressure—intramural circulation of the bowel—stasis—edema

The dehydration, pain, and reflex and circulatory changes are found in all cases of intestinal obstruction whether or not the obstruction is simple or strangulating. However, when the latter condition, that of strangulating obstruction, obtains, there are, in addition, further important effects concerned with the circulation in the obstructed bowel segment.

Circulatory effects While simple obstruction will produce circulatory changes in the bowel wall by an increase of the intraluminal pressure because of distention from accumulating fluid and gas, these changes are far less extensive and significant than those which occur when the blood supply of the bowel is impaired from lesions involving the vascular radicals of the mesentery. It

should be noted in this connection that much of the experimental investigation previously carried out to determine the effects of impaired mesenteric circulation on the bowel loses its significance when applied to human subjects for the reason that the mesenteric vascular patterns in the human being are considerably different from those found in the usual experimental animals employed, e.g., dogs, cats, and rabbits (29, 31).

Certain generalizations can, however, be made regarding mesenteric vascular lesions occurring in obstruction based upon experimental and clinical evidence (5, 10, 12, 13). Regardless of the nature of the specific causal agent producing the impaired blood supply, the extent and character of the circulatory changes in the bowel wall are generally dependent upon the following factors:

- 1 The locality of the lesion producing the circulatory interference with respect to the mesenteric vascular pattern

- 2 The rapidity and completeness with which the vessels are occluded

- 1 When the lesion is at or close to the origin of the principal mesenteric vessels, the area of the bowel which will be affected by impaired circulation will be greater. Conversely, the further from the origin of the main vascular radicals these lesions occur, the less will be the involvement. A single lesion, e.g., embolus, thrombus, occluding the main mesenteric trunk will produce extensive impairment involving the entire small bowel and part of the large one, while a single similar lesion occurring in one of the lesser radicals close to the bowel wall may produce no detectable change whatever. This is apparent from an examination of the mesenteric vascular pattern in which the anastomotic channels increase progressively as they pass from their origin distally toward the bowel. If, however, a sufficient number of the smaller radicals are consecutively involved, even when the site of obstruction is close to the bowel, the circulation in the bowel may be severely impaired (5, 10, 12, 13).

- 2 As with other body parts, a lesion which suddenly and completely interrupts the blood supply produces more immediate and severe effects upon the bowel than one in which the occlusion occurs more gradually. In the latter instance the decreased blood supply through the occluded vascular channels may be to a variable extent compensated for by the development of a collateral circulation through channels not affected by the lesion so that the changes incident to circulatory deficiency take place more gradually and are less liable to jeopardize bowel viability. Whenever the blood supply to the bowel is reduced below that

necessary for the maintenance of its normal physiological activity, a condition of anoxia of the tissue supervenes. Initially, the smooth muscle of the bowel wall under the stimulus of the anoxic state increases the force and frequency of its contractions and, therefore, peristalsis is temporarily augmented. If the impairment to the blood supply persists, the bowel ultimately loses its power of contractile response, becomes spastic, then flaccid, and, finally, completely atonic. If the circulatory embarrassment continues, the final result is necrosis of the bowel wall with discharge of its bacteria-laden content into the peritoneal cavity. Nor is it essential for the bowel to become necrotic before pathogenic organisms pass through its walls, for it has been demonstrated that organisms capable of producing peritoneal inflammation changes can gain access to the peritoneal cavity through bowel wall which is not actually necrotic, but of which the viability has been markedly impaired (19, 26). As has been previously stated, the rapidity with which these changes occur is, in general, proportional to the rapidity and completeness of the production of circulatory impairment. If it is recalled that distention of itself will produce circulatory impairment within the bowel wall, the fact is apparent that when an abnormal degree of distention is present together with a lesion which occludes the circulation in the mesenteric vessels, the impairment is greater than if there were no distention. In other words, the presence of distention in strangulating obstruction increases the circulatory impairment initially produced on occlusion of the mesenteric vessels. Moreover, when the circulation to the bowel is impaired sufficiently by a lesion involving the mesenteric vessels, distention is bound to occur for the reason that circulatory embarrassment alone will produce obstruction.

A summary of the progressive effects of an embarrassed circulation may be represented as follows:

Circulatory embarrassment—*anoxia of the bowel musculature—hypermobility—spasm—flaccidity—dilatation—loss of viability—perforation*

Toxic factor Much has appeared in experimental and clinical literature concerning the presence of absorbable toxic products formed in simple or strangulating obstructions (4, 37). Before the demonstration that distention incident to obstruction can of itself produce fatal disturbances largely through alterations in the fluid balance (6, 7, 9, 15, 16, 17, 27, 32, 34), it was assumed by many that the lethal effects observed in obstruction were in a great measure accounted for by the formation of toxic products in the static bowel

the splanchnic afferent nerve fibers of the mesentery, and any palpation which does not change either of these has little effect upon the pain. There are, however, as previously noted, outstanding exceptions. These occur in closed loop obstructions in which a definite mass can be palpated, or in instances in which perforation of the bowel has actually occurred. In these instances the mass palpated may be extremely sensitive to pressure, or, when perforation has occurred, generalized tenderness is present throughout.

4 Unless perforation has occurred in the obstructed area with a resulting peritonitis, true muscular spasm is rarely present. The abdomen, dependent upon the amount of distention or fluid contained at the time of examination, has rather a doughy consistency upon palpation, and this condition obtains until such time as true muscular spasm incident to perforation and peritonitis appears. It should be remarked, however, that in most instances there is usually a considerable degree of voluntary muscular splinting which may be confused with true reflex rigidity. However, by persistent effort the difference can be distinguished.

5 The presence of a mass is an inconstant feature. This depends upon the specific nature of the obstruction and its location. It is also dependent to a considerable extent upon the thickness and character of the abdominal wall. If the mass is superficial in a thin-walled individual such as a child, or an elderly person lacking muscular tone, continued attempts may reveal an ill-defined tender tumor. Also careful observation may reveal an inequality in the contour of the abdomen. Obviously this is significant only when present, and failure to demonstrate it is of little consequence in effecting diagnosis. It should be remembered that not infrequently the location of the mass may render it incapable of abdominal palpation, but it may be reached by rectal examination. The obvious necessity of including rectal, and, in females, vaginal examinations, is therefore emphasized.

Character of the peritoneal fluid In practically all instances of strangulating obstruction, whatever the specific causal agent, the extravasation of blood into the peritoneal cavity occurs sooner or later. The mechanism by which such extravasation occurs is obvious from the foregoing statements and little additional comment concerning it need be made. There are, however, certain features which are of practical interest.

As has been pointed out, intra-abdominal lesions producing strangulating internal obstructions characteristically involve the mesenteric

vessels. These lesions (volvulus, adhesive bands, intussusception) seldom, if ever, completely occlude both the venous and arterial channels at onset. Usually the thinner walled veins are compressed first with a resultant rise in the venous pressure, but the arterial pressure is little affected. Then as the process progresses with edema, the arterial flow is gradually reduced or completely shut off. However, in the main, aside from actual rupture of the thinner walled capillary and venous channels, the extravasation of the blood is produced early by the elevated capillary pressure maintained against an impeded venous return. The result is a passage of the fluid and cellular elements of the blood into the lumen of the obstructed bowel and into the free peritoneal cavity. The extent to which this occurs depends upon the number of the mesenteric vascular channels involved and the degree of compression the obstructing lesion produces. This is the usual sequence of events in by far the great majority of strangulating obstructions. The only instances of such obstruction not characterized by at least some suffusion of blood into the peritoneal cavity are those in which the condition of bowel obstruction and the circulatory embarrassment arise from a complete or partial occlusion of arterial radicals without any impediment to the accompanying venous channels (primary mesenteric arterial thrombosis, arterial embolism, or dissecting aneurysm). The latter are, however, of far less frequency than the usual lesions which produce strangulating internal obstructions (adhesive bands, internal herniations, volvulus). The point made by the immediately foregoing statements is that in most instances of strangulating internal obstruction, bloody peritoneal fluid is invariably present within 4 to 6 hours following onset if the lesion producing the obstruction and vascular occlusion is mechanical, but the absence of bloody peritoneal fluid by no means abolishes the possibility of a strangulating obstruction on a purely vascular basis (mesenteric arterial thrombosis).

The value of the presence of bloody peritoneal fluid as a pathognomonic sign of strangulating internal obstruction is further lessened when it is recalled that other acute abdominal conditions commonly, if not invariably, produce it (torsion of pedunculated ovarian cysts, ectopic pregnancy, hemorrhagic pancreatitis).

In spite of this multiplicity of conditions also characterized by the presence of bloody peritoneal fluid, it may be confidently stated that in instances of obstruction the presence of bloody peritoneal fluid determined preoperatively by paracentesis provides one of the most indicative

signs in the differentiation of simple from strangulating obstructing lesions

It is rarely that the quantity of blood loss in a strangulated obstruction is of sufficient degree to produce signs of acute blood volume deficiency, as evidenced by the fact that in most, if not all, instances of strangulating obstruction, the blood studies invariably show concentration with elevation of the hemoglobin and cellular elements, in contrast to the hemodilution shown in blood loss. It should be noted, however, that sufficient blood may on occasion be extravasated into the peritoneal cavity to produce signs of peritoneal irritation with the result that signs of fluid appear, as exemplified by tenderness and reflex spasm.

X-Rays While x-ray studies of the abdomen are an essential part in the establishment of the presence of small bowel obstruction, they are of particular consequence in the differentiation between the simple and strangulating types (23, 25, 30)

The nature of the agents causing most instances of internal strangulating obstructions is such that obstruction of a "closed loop" type is produced. That is to say, the lumen of the bowel is mechanically occluded at two points by a single constricting lesion with a compression of the mesentery and its vascular radicals at the site of the constriction and an open lumen of the bowel between the constricted areas. Upon x-ray this usually appears as an isolated loop showing gaseous distention of small bowel pattern. The presence of such an isolated loop of distended small bowel in the presence of other diagnostic features may be considered almost pathognomonic.

It should be pointed out, however, that it is possible and of frequent occurrence that a closed loop obstruction of the strangulating type can exist but the closed and distended loops cannot be exactly identified in the film. Visualization depends largely upon the time factor or the period during the course of the obstruction at which the films are taken. An isolated loop is more prone to be distinguished early in the course of the obstruction, before distention of the bowel above the actual obstruction site becomes visibly dilated and distended with the increasing increment of fluid and air. When the latter condition occurs, as it inevitably does later in the progress of the obstruction, it becomes impossible to differentiate the isolated loop from the general distention pattern. It is not intended to imply that in all cases in which an isolated loop of distended small bowel is demonstrated by means of the x-rays that the condition is inevitably one of strangulating obstruction, for there are undoubtedly rare in-

stances of isolated loop obstruction which are of the simple type with only occlusion of the lumen and no embarrassment of the intestinal circulation, but these are distinctly few. Nor can it be assumed that because no isolated loop is demonstrable that no strangulating obstruction is present. However, the presence of a single loop, if found together with the diagnostic features, may generally be regarded as the strongest evidence of strangulating obstruction.

It not infrequently occurs that together with a visible isolated loop, the presence of fluid may also be noted in the abdomen. This is apparent by the familiar hazing of the outlines of the distended bowel and viscera, and when present is strong corroborating evidence, since the transudation of fluid into the peritoneal cavity inevitably occurs during the course of strangulating obstruction.

Miscellaneous features There are, in addition, certain features of a minor nature, a consideration of which may influence judgment in the individual case. These are diverse in nature and difficult of categorical placement, and therefore are included under a miscellaneous heading.

Certain specific types of internal strangulating obstructions are associated with the extremes of age as, for example, intussusception and Meckel's diverticulum in children, and volvulus of the large bowel (sigmoid) and mesenteric thrombosis in individuals of advanced age.

The possible existence of a precedent or co-existent pathological state, which although not directly related to the obstructive conditions may either markedly influence the progress of the latter or be influenced by it, must certainly be taken into account. This remains a consideration particularly in the older age groups in which such disabilities as diabetes, cardiac lesions, anemia, and renal and extrarenal azotemia are common. The importance of recognition of such associated incapacities as factors complicating diagnosis and treatment is so obvious as to require little comment.

It should also be borne in mind that on occasion simple obstruction may, by the unrelieved progress of the local disturbances located in the obstructed bowel segment (engorgement, edema, and the intraluminal collection of fluid), be converted into obstruction of the internal strangulating type. If this possibility is not recalled, it may be erroneously assumed from the history of gradual onset, delayed initial vomiting, and other initial features, that the obstruction is still of the simple type, which indeed it was at the onset. Thus the intercurrent strangulation factor may be missed with fatal result. It is wise, therefore,

to regard any increase in the severity of signs and symptoms of internal obstruction with considerable suspicion

A history of previous laparotomy and the presence of abdominal scars, although perhaps of minor import, may be mentioned. While the formation of postoperative adhesions is recognized as a prime causal factor in the production of internal obstruction of either the simple or strangulating type, it has been frequently observed that in the absence of such adhesions and, therefore, in the absence of any scars or previous operative history, obstruction of sudden onset and severe progression of symptoms are apt to be of a strangulating nature. This is explained on the basis of the fact that aside from adhesions which are the most frequent cause of natural obstruction of either type (simple or strangulating), the next most frequent specific causal lesions (volvulus, intussusception, internal hernia, thrombosis) produce internal obstructions of the strangulating type.

It is within the experience of everyone who has had to deal frequently with instances of obstruction that what was diagnosed as the internal strangulating obstruction preoperatively is found to be due to external hernia and therefore an obstruction (definition) of the external strangulating type. This is prone to occur in extremely obese individuals with great thickness of the abdominal parietes in whom abdominal examinations in general, and examinations of the hernial orifices in particular, are apt to be difficult. Actually such an error, aside perhaps from the technical consideration of the placement of the exploratory incision, is not a grave one provided the strangulating character of the obstruction is recognized. It does, however, serve to re-emphasize the often reiterated point that extremely careful examination of all external abdominal areas through which hernias are prone to occur is necessary.

THERAPEUTIC CONSIDERATIONS

There is no question of the urgent indication for immediate surgery once the diagnosis of strangulating obstruction has been positively made. It may also be added that when, in spite of careful consideration of the diagnostic criteria, doubt still exists as to whether the obstruction is of the simple or strangulating type, surgical intervention as soon as possible remains mandatory. While there is no question concerning the indication for surgery in positive and even doubtful instances of strangulating obstruction, there remain three other practical considerations

TABLE 1—SUMMARY OF THE DIFFERENTIAL DIAGNOSTIC FEATURES DISTINGUISHING STRANGULATING FROM SIMPLE ACUTE SMALL BOWEL OBSTRUCTIONS

	Strangulating Obstructions	Simple Obstructions
Pain	Onset sudden and fulminating Type severe cramplike present continuously with peristaltic exacerbations	Onset gradual less sudden Type less severe cramplike but tends to disappear in periods of peristaltic inactivity
Vomiting	Onset tends to occur at onset of pain Type sustained continuous, severe little relation to peristaltic action.	Onset gradual usually at a considerable interval after onset of pain Type periodic tends to be simultaneous with peristaltic action.
Shocklike manifestations	Onset appear early almost at onset. Type persistent with progressive severity	Onset appear much later Type less severe
Response to conservative therapy (decompression and hydration)	Poor response—symptoms and signs tend to persist and progress in spite of all measures	Good response—symptoms and signs tend to improve with conservative measures
Peritoneal fluid	Invariably bloody—frequently demonstrable with x rays	Clean—rarely present in excess
Presence of isolated loop	Frequently present and demonstrable with x rays	Rarely present.
Abdominal scars	Frequently present.	Frequently present.
Abdominal mass	More often present and detectable by abdominal or rectal palpation	Rarely present or detectable.
Abdominal tenderness	More frequently present and marked	Less frequently present and less marked.
Abdominal spasm	More frequently present and marked	Usually absent when present, less marked
Blood studies	Show dehydration and hemoconcentration—present in spite of therapy	Show dehydration and hemoconcentration—tend to ameliorate with therapy

- 1 The time at which operation is to be carried out
 - 2 The preoperative preparation
 - 3 The specific type of surgical procedure
- Concerning the first, it has already been stated that the indication for surgery is immediate. The principal concern, therefore, in this regard is whether or not the general condition of the patient is such that the necessary procedure can be without. It should be recalled in this connection that in instances of strangulating obstruction, despite adequate treatment of the patient's systemic circulatory disturbances (dehydration and shock), his general condition does not materially improve and there is a marked tendency toward fatal circulatory collapse. Any attitude of delay in operation to await an expected response to conservative measures of treatment is extremely dangerous. It is also to be remembered that,

although the response to the usual measures employed in combating the systemic disturbances is poor as long as the condition of obstruction persists, when the obstruction has been relieved by the indicated operative procedure, the decrease in systemic manifestations is dramatic. On this account the general precept of immediate operation while the usual measures for correction of the patient's circulatory depletion are in progress is advanced.

Concerning the preoperative preparation of the patient, in addition to the administration of fluid and blood, the most important single measure is that of instituting decompression. It is to the advantage of the surgeon as well as to the patient if the patient can be successfully intubated prior to undergoing operation, and every effort should be made to do this provided it does not entail any considerable delay. By successful intubation is meant the passage of the long tube, of whatever type selected (Johnston, Miller-Abbott), past the pylorus and well into the duodenum so that decompression may be begun during, and carried on after, operation. Accomplishment of this particular procedure not only facilitates any technical procedure during operation by lessening the distention of the distended segments of the bowel, but also obviates the necessity of intubating critically ill patients subsequent to operation for the control of inevitable ileus (1, 20, 21, 28, 30).

Regarding the latter statement, some mention is essential of the repeated criticism that intubation with the long tube is a dangerous procedure in strangulating obstruction. This criticism is apparently based upon unfortunate fatalities resulting in strangulating obstruction when long tube decompression was relied upon as the sole and principal form of treatment. So far as the writers are aware, no observer of recognized experience has ever recommended long tube decompression as a substitute for surgical intervention in strangulating obstruction. The statement has been made, and with ample justification from clinical experience, that long tube decompression together with restoration of the fluid balance are indicated in all instances of intestinal obstruction (9, 22, 23, 30, 42). In simple, nonstrangulatory obstructions of the mechanical type in which intubation and decompression have been successfully carried out, subsequent surgery may be an elective procedure because the lethal effects of distention are thereby controlled and there is no danger of peritonitis from perforation. In simple obstructions of the ileus or paralytic type, intubation decompression is practically the sole reliable form of therapy (23, 41). When dealing with

strangulating obstructions, however, there is no substitute for the immediate operative relief of the obstruction and the embarrassed blood supply to the obstructed part, and long tube decompression is advocated only as an adjunct therapeutic agent to facilitate the operative procedure and minimize the usual postoperative ileus. It is apparent, therefore, that criticism of the use of long tube decompression in obstructive cases arises mainly from the reliance upon it as the sole form of therapy in instances of obstruction of the strangulating type in which surgery is urgently indicated. This error is patently one of diagnosis, a failure to appreciate the strangulating nature of the obstruction, and in no way constitutes a reasonable indictment of long tube decompression, which is a most valuable form of therapy. It would seem almost as rational to criticize the use of knives because of unfortunate instances in which vital structures were unintentionally cut because of error or oversight on the part of the operator.

It is not within the scope of this article to outline the details of the various types of surgical procedures which may be indicated, for these are largely determined by the particular conditions encountered in the individual case. There are, however, certain general observations which may be ventured.

In all instances of obstruction a decision must be made as to the viability of the obstructed bowel segment. This probably constitutes the most important single decision during the operative procedure, because the critical matter of resection of the bowel in question depends upon it. The state of bowel viability, in spite of the recent ingenious procedures devised for its determination, remains in the last analysis a matter of individual judgment on the part of the surgeon. Frequently, the state of viability is so doubtful as to tax the acumen of the most experienced. It has been the observation of the writers that the common error is in the resection of viable bowel rather than the failure to remove necrotic bowel segments. While the former mistake is certainly preferable to the latter, it is believed that the margin of error can be considerably reduced by a longer period of observation of the questionable bowel than is ordinarily advocated (20 minutes). An additional interval of observation, provided the patient's condition permits, may prove unquestionable viability, and therefore preclude resection of a segment which for the initial 20 minutes appeared permanently damaged.

An additional point of emphasis bears reiteration since grave mistakes too frequently occur. This concerns the performance of complete ex-

ploration of the small bowel rather than confining attention to what appears to be the obviously obstructed area. Not infrequently the bowel may be obstructed at more than one point and a second obstructive area may be easily missed unless its entire extent is explored. Moreover, while the obstruction may occur only at a single point, other segments may be affected by conditions correctable at the time of operation and which if unrelieved may be capable of producing subsequent obstructive episodes.

It is scarcely necessary to emphasize that the standard antibiotics, penicillin, streptomycin, and sulfone derivatives should be employed as therapeutic adjuncts in combating possible septic complications in individual cases (3, 35).

CONCLUSIONS

Internal strangulating obstructions of the small bowel constitute a group of acute surgical emergencies frequently misdiagnosed preoperatively.

Errors in diagnosis arise because of the concealed origin of the obstruction, the variety of acute abdominal lesions with which the obstruction may be confused, and the absence of any single pathognomonic sign by which the condition may be positively identified.

Correct diagnosis is largely a matter of evaluation of the signs and symptoms enumerated.

The lethal as well as the pathological changes giving rise to the presenting signs and symptoms arise from distention and circulatory effects.

Prompt surgical intervention in positive and doubtful cases is urgently indicated.

The specific surgical procedure is determined by the nature of the obstructive lesion and the individual experience and judgment of the surgeon.

SURGERY OF THE HEAD AND NECK

HEAD

Internal Wire Immobilization of Jaw Fractures
J B BROWN, M P FRYER, and F McDOWELL.
Plast Reconstr Surg, 1949, 4 30

Various methods of treating complicated and compound fractures of the jaw appear in the literature, including open bite splints, overhead plaster-cap, traction devices, complicated dental appliances, and external fixation

No single method of immobilization is applicable to all patients, and whatever will give the best fixation is the ideal method. A very simple and direct method is that of internal wire fixation, which may be used alone, or may be combined with dental arch supports, interdental wiring, direct bone wiring, and dental fixation

When enough teeth are present in the proper position to allow wiring the jaws in proper occlusion, this is the method of choice. No. 24 or No. 26 stainless steel wire is used between the teeth and, for further stability, an arch of No. 24 wire is looped around the posterior teeth and twisted together in front with anchors of No. 28 wire to the individual teeth. Loop, eyelet, and button wiring, elastic loop fixation, and acrylic splinting are variations of technique which may be efficacious

When, for some reason, interdental wiring would not be sufficient, as in patients with lack of available teeth, patients with fractures of the symphysis, or with angle fractures with posterior fragments displaced into the upper buccal fornix and compounding into the mouth with infection and sloughing, the fractured lower jaw may be immobilized by a Kirschner wire, .05 to .08 inch, driven across the fracture site

In an edentulous mouth, internal wires can be used in conjunction with circumferential wires around the patient's dentures

The technique of introduction of the internal wire is to drive the wire across the fracture site below the nerve canal with a power drill while another person holds the fragments in reduction

Asepsis should be as good as possible, the skin and periosteum nicked, the wire cut to minimal length to prevent "whipping," and a power drill used with a speed fast enough for penetration, but not fast enough to produce necrosis

A fixation dressing of mechanics' waste is a further support to the jaw and helps prevent hematomas and soft tissue swelling, decreases the chance of infection, and increases the patient's comfort

Complications have been slight, usually confined to slight drainage around the pins

EYE

Experimental Studies on the Pathogenesis and Treatment of Ocular Tuberculosis. ALAN C WOODS *Brit J Ophth*, 1949, 33 197

The author reports his experimental studies over a 12 year period on the pathogenesis and treatment of ocular tuberculosis. The objective of the investigation was to determine the following

- 1 Whether Rich's law holds true in localized ocular tuberculosis. This was determined by the effect of the number and virulence of the infecting organisms on the resulting ocular lesion, the influence of local tissue sensitivity, the influence of systemic immunity, and the relation of cutaneous and ocular sensitivity

- 2 Whether enhancement of local resistance or immunity is possible

- 3 The effect of desensitization on the local ocular lesion

- 4 The possibilities of sulfone and antibiotic treatment in ocular tuberculosis

It was previously supposed that the phenomena of hypersensitivity and immunity were interdependent and that allergy was responsible for immunity. However, Rich demonstrated in 1929 the independence of hypersensitivity and immunity, and that a previously tuberculous animal could be completely desensitized to the extent that not only the soluble bacterial products but even living bacilli injected into the skin would cause no local inflammatory reaction. Moreover the resistance to dissemination of the bacilli or immunity to reinfection was totally undisturbed. Rich's law may be expressed in the following manner

$$\text{Lesion} \propto \frac{\text{Number and virulence of bacilli} \times \text{allergy}}{\text{Resistance}}$$

It has been known for a long time that experimental ocular tuberculosis took quite a different course in the normal animal from that in an animal previously infected with tuberculosis (the immune allergic animal)

A virulent human strain of tubercle bacilli was used in the experiments. It was injected into the anterior chamber of the eye of a normal or immune-allergic rabbit in proper dose, as well as systemically to develop a self-limiting disease from which recovery occurred with an immune allergic status

It was found that Rich's law for the pathogenesis of tuberculous lesions holds true in localized ocular tuberculosis. The factors which govern the course and character of the lesion are the number and virulence of the infecting organisms, the degree of tissue hypersensitivity present, and the amount of

SURGERY OF THE HEAD AND NECK

the resistance developed by the host. These studies also explain the relative cutaneous allergy often present in animals and man with inflammatory tuberculous lesions of the eye.

As a result of this concept of the pathogenesis, many therapeutic approaches are provided, such as

- 1 Enhancement of immunity. No specific measures along this line have been developed so far.
- 2 Removal of the fatal tissue hypersensitivity. This can be accomplished by the use of tuberculin as a desensitizing agent. Tuberculin has a distinctly beneficial effect on the clinical course of the lesion.
- 3 Direct attack on the tubercle bacilli. This may be accomplished best with a combination of streptomycin and promizole.

Promizole is a nontoxic sulfone. It can be administered to human beings in doses as high as from 12 to 15 gm daily with comparative safety. Penicillin alone had no effect whatsoever on the clinical lesions, but streptomycin combined with promizole appeared to eradicate the bacilli from the infected tissues in a large per cent of the treated cases and curtail their growth and virulence in the remaining cases.

JOSHUA ZUCKERMAN, M D

Diathermy Cauterization of the Ciliary Body for Glaucoma

SAMUEL J MEYER Arch Ophth, Chic, 1949, 41: 417

Cyclodiathermy puncture is indicated in cases of (1) glaucoma with a flat anterior chamber in which previous trephination or iridectomy has been unsuccessful, (2) aphakia with secondary glaucoma, (3) secondary glaucoma due to iris prolapse, (4) hemorrhagic glaucoma, and (5) primary glaucoma in which the chamber angle is obliterated. Other operations are of questionable merit.

The author operated on 142 patients and the results obtained in 136 are reported. There was complete relief of pain in 94 patients (74%), and reduction of intraocular pressure below 35 mm of mercury in 42 patients (33%).

The operation is usually performed inferiorly, and retrobulbar and subconjunctival procaine anesthesia is used. The conjunctiva in the region of the insertion of the inferior rectus is opened and the incision is extended in an arc nasally and temporally to the insertions of the medial and lateral rectus muscles. The sclera is dissected clean to within 1 or 2 mm of the limbus. Diathermy needle punctures (45 milliamperes for $\frac{1}{2}$ to 1 second) are then placed about 5 mm apart in a zone 2 to 4 mm wide just anterior to the insertion of the inferior rectus and extending in an arc to within 2 mm of the insertion of the horizontal rectus muscle. The conjunctiva is closed with continuous black silk and atropine ointment is instilled.

To prevent corneal complications, the diathermy needle must never be placed within 2.5 mm from the limbus. The needle must be not longer than 5 mm and 0.18 mm in diameter, and should have a shoulder stop to prevent too deep penetration.

FRANK W NEWELL, M D

Successful Diathermy Treatment of Recurring Retinal Hemorrhage and Retinitis Proliferans Report of a Case

F H VERHOEFF

Arch Ophth, Chic., 1948, 40: 239

In most cases of retinal hemorrhage the patient gives a cutaneous reaction to tuberculin, and in the cases in which the retina has been examined microscopically, nodular foci of epithelial cells have been observed along the veins. These facts constitute strong evidence that the condition termed "periphrisis adolescentum" is an entity, that it is caused by tuberculosis, and that to it most cases of called Eales's disease belong. It is uncertain whether the periphrisis is directly hematogenous or results from dissemination of the infection by way of the vitreous.

Various treatments were used, including injections of tuberculin which have been of doubtful value. So far, the case presented has been the only instance of recurring hemorrhages in which diathermy treatment was employed. The entire hemorrhagic region was subjected to diathermy. Numerous additional hemorrhages produced by this treatment seemed alarming at the time, but all the blood had disappeared at the end of about 3 weeks, and up to the time of this report (15 months after the second episode) there has been no recurrence of hemorrhage in the eye.

Diathermy may possibly be of benefit, not only in selected cases of tuberculous periphrisis but in cases of retinal vascular obstruction from any cause. It may establish communication between retinal and choroidal vessels and thus restore retinal circulation. The appearances in some of the treated areas indicated that such a communication had been made. It would seem, therefore, that attempts to establish, by this or other means, such collateral circulation should be made in all cases of impending blindness from obstruction of the retinal vessels. These cases would include those of partial obstruction of the central vein or artery, cases of pronounced sclerosis of the retinal vessels with impending impairment of central vision, and early cases of circinate retinitis. In cases of complete obstruction of the central vein, the treatment might at least prevent the development of hemorrhagic glaucoma. It might even offer some hope in cases of diabetic retinopathy. The possible establishment of a collateral circulation arising from the disk or of retinitis proliferans from the affected vessels in the vicinity. Here, of course, the affected vessels not safely be obliterated by diathermy, but the establishment of a collateral circulation near the might relieve the venous congestion and thus the proliferation of new vessels.

MICHEL LOUTFALLAH,

The Diagnosis of Retinoblastoma

BEDELL Arch Ophth, Chic, 1948, 40: 311

Three types of the common yellow pupillary complexes are included in the author's definition but not detachment of the retina (which

times be confusing), nor the rare cysticercus of the vitreous. The subject of retinoblastoma is presented with 6 case histories, and a description of the ocular signs which led to enucleation in 5 cases, and to the unmistakable diagnosis of angiomatosis in 1 case.

The first case was of interest because of the early inflammatory reaction which led the parents to delay in bringing the child for diagnosis. With a tumor of such rapid growth, it is doubtful whether anything could have prevented the fatal outcome 1 year after the first sign of the retinoblastoma. In the second case there was a slower rate of growth and the absence of recurrence. The child was first seen when she was 26 months old because something was wrong with the left eye. Nine months before, the parents had noticed that the left pupil had a peculiar yellow color, and lately they had noted that the eye rolled about as though it could not see. The diagnosis was retinoblastoma. In this case the tumor was large and was growing rapidly in and on the retina. After 4 years, there has been no metastases or recurrence, so that the outcome seems favorable.

The third case was of unusual interest because of the appearance of the vessels which resembled angiomatosis, the fundus picture which suggested a growth, the pathologic type of the tumor, and the development of multiple metastases. There were many fine dustlike cells in the vitreous. The disk was slightly oval, but even under the powerful light of the camera it could not be sharply outlined. The veins of the upper half of the fundus were larger than normal, and the superior temporal branch was beaded, the veins in the lower portion were not remarkable. A short time later, the child complained of pain. There was an area of hypopyonlike sediment measuring 1 mm in the anterior chamber. The eye was enucleated, and the diagnosis was leukosarcoma of the choroid.

The fourth case was that of a 4 month old girl born in the sixth month of pregnancy. The iris was dark, with a deep yellow-gray reflex visible through the pupil which measured 3 mm, the anterior chamber was very shallow. On section, the diagnosis of retrolental fibroplasia was verified.

In the fifth case, the diagnosis of angiomatosis seemed unmistakable, and the changes characteristic of this condition, of a bizarre type, were well shown except for the angoma itself, which was outside the photographic field, in the extreme field visible with the ophthalmoscope.

The sixth case was that of an 8 month old baby who, according to the parents, did not see as well as the other children. With the child under ether anesthesia, the reflex was found to be produced by a smooth-surfaced, large yellow layer without definite boundaries but limited mainly to the temporal half of the retina. Enucleation was done because the eyeball was obviously extensively involved and sightless, and all previous treatment had been unavailing. The diagnosis was glaucoma secondary to uveitis and retinitis, classifiable as Coats' disease.

MICHEL LOUFFALLAH, M D

EAR

Prefabricated Autogenous Ear Cartilages H ELLIOTT BLAKE *Brit J Plast Surg*, 1949, 1 220

The chief difficulty in the provision of support for a reconstructed pinna is to find an inlay which is sufficiently rigid and yet thin enough to pass as a reasonable likeness of normal ear cartilage. Prior to June, 1947, the author buried sheets of costal cartilage beneath the postauricular skin, later excavating and skin grafting at a deeper level, thus providing a skin-cartilage-skin sandwich as the supporting element of the reconstructed pinna. This was flat with no concha, was limited in size by the amount of hairless postauricular skin available, and short in its upper third as compared with a normal ear.

The additional skin is provided first, usually by a tubed pedicle from the upper arm. Later a laminated sheet of cartilage is added, which is shaped to a reasonable likeness of the pinna by burial in the subcutaneous tissue of the abdomen between thin sheets of tantalum.

Peer and Aufricht previously have used buried autogenous cartilage in shaped molds, but they placed reliance for rigidity on the massive solidity of their molds. With use of the following method, the author aims to produce an extremely thin sheet of cartilage, as much like normal ear cartilage as possible, which needs no further shaping, the rigidity depending solely on its multiple curves, and its resilience on its thinness.

The cartilage is taken from the superficial two thirds of the eighth and ninth costal cartilage, and the superficial reflected perichondrial flaps are then resutured. At the abdominal end of the paramedian incision, a subcutaneous pocket is left for the mold. The cartilage is cut into coarse flakes, spread and squeezed tightly between the plates of the tantalum shaping cup, and buried beneath the abdominal skin.

The shaping cup is made of 0.015 cm tantalum sheet molded to the shape of a modified ear, perforated by multiple holes to allow the passage of blood, lymph, and fibrous tissue. Ledges keep the two sections separated 1 to 2 mm apart, thus determining the thickness of the cartilage mold. Curves, ridges, and depressions have been intensified in the anterior plate in later models to give more rigidity where needed.

The mold is removed from its pocket after from 3 to 7 months, and is resilient and correctly shaped.

Histologically the cartilage flakes appear as normal living cartilage, firmly bound together by fibrous tissue in which capillaries can be seen. There is firm, fibrous union between flakes after a period of 5 months, but no fusion of cartilage flakes.

The cartilage plate is trimmed, and a few holes are punched into it to allow fibrous tissue to grow through and anchor it in place. It is then fitted into the bag of ear skin and a pressure dressing is applied.

Of the 7 completed cases, 2 showed flaccidity due to insufficient rigidity of cartilage, 1 showed crumpling due to insufficient skin covering, the other 4 were sufficiently encouraging to justify continuing the

SURGERY OF THE HEAD AND NECK

method, and attempting to prefabricate nasal cartilages even thinner and more complex in shape
 LOUIS T BYARS, M D

The Microtic Ear EDGAR M HOLMES *Arch Otolaryngol*, 1949, 49 243

The author briefly outlines the embryology of all portions of the ear according to best authorities and shows how the inner ear develops separately from the middle and external ear and how the pinna is the last part of the ear to develop. He thus justifies the known fact that congenital anomalies may affect any portion of the ear separately. He classifies congenital anomalies of the external and middle ear as follows:

- 1 The ear which is small over all
- 2 Lack of development of the upper part of the auricle and helix.
- 3 Adherence of the usually free portion of the upper part of the auricle to the side of the head
- 4 Agenesis of the entire auricle except for the concha and lobule
- 5 Agenesis of the entire auricle. Only a mass of skin covered cartilage is found in this case although the lobule may be well formed

It is usually only in this last case that the meatus may be partially or totally obliterated by fibrous or bony tissue. When the canal is nearly or entirely obliterated the structures of the middle ear are often deformed with absence or deformity of the malleus, membrane and ossicles. This particular condition is also frequently associated with an asymmetry of the face and a partial agenesis of the ramus of the mandible on the corresponding side. Although the bone condition may be normal in these cases, an attempt to re-establish hearing by the formation of an external auditory meatus usually fails partially because of the presence of agenesis in the middle ear structures. The author has hopes that this may be rectified to some extent by the performance of fenestrations on these patients. Bone conduction hearing aids may also be used.

Surgical procedures for the correction of the deformities Nos. 2, 3, 4, and 5 are described. The author counsels against the performance of any of the cosmetic operations on women when the microtic ear can be covered with hair, and also against the performance of any type of reconstruction of an external auditory canal in an individual who has good hearing in one ear because of the possibility of injuring an abnormally located facial nerve. The use of the newer, better prosthesis may be the answer to the more severe deformities. It can never be entirely satisfactory, however, because of the ever-changing color of the normal skin.

WILLIAM K WRIGHT, M D

Hydrodynamics and Hearing. The Operative Relief of Otosclerotic and Nonotosclerotic Deafness and Its Relationship to a Hydrodynamic Hypothesis of Hearing OTTO POPPER *Arch Otolaryngol*, 1949, 49 335

The author believes that because of the development of the fenestration operation, the theories of

hearing should be reorganized. He believes that otologic teaching should be revised, and it is his belief that the hydrodynamic hypothesis offers a satisfying explanation for many of the phenomena in hearing.

He divides his leading questions into several parts, as follows:

1 What is meant by hydrodynamics? It is a fact that the inner ear consists of fluid columns which communicate freely with each other and thus form a perfect hydrodynamics system, rigidly enclosed, but with mobile sealed ends, these ends being the stapes and the round window.

2 How does fenestration restore hearing, and is such restored hearing normal? In otosclerosis the stapes is gradually immobilized and ceases to function as an escape valve, and the perilymph is impeded to pressure, and the perilymph is impeded. The organ of Corti thus receives a weaker stimulus, and deafness is established. Clinical otosclerosis is not a deafness, but a breakdown of the hydrodynamic system, with a stapelial fixation converting the latter into a tube rigidly sealed at one end, and deafness is thus the predominate symptom of this breakdown. The fenestration operation restores hearing by forming a new escape valve, removes the mechanical barrier, restores the hydrodynamic system, and re-establishes mobility of the perilymph.

3 The stapes, the perilymph, and the round window membrane. What is their protective role? The stapedius muscle contracts on loud stimuli and directly protects the organ of Corti from injury, and the whole organism from the perils of surprise attack. The contraction of this muscle controls excessive excursions of the perilymph and partially immobilizes the perilymph in cases of extreme stimuli, also by its contraction, it aids the ear in picking out certain portions of the sound spectrum.

4 Why are the organs of balance and of hearing so intimately related to one another? These are related because the entire labyrinth is formed for the interception of minute differences of pressure—continuous, as in the vestibular apparatus, or periodic, as in the cochlea.

The author discusses the function of the ossicles. The stapes (1) accommodates excursions of the perilymph in hearing, (2) creates differences in pressure between the two windows (a) for the protection of the organ of Corti against injury, and (b) for the protection of the whole organism. The function of the malleus is (1) to close and center the capitulum of the stapes so that movement caused by contraction of its muscle will be restricted to a prescribed orbit or plane, (2) to oppose the tone of the stapedius muscle and prevent the permanent deafness that would result if the footplate were pulled out of the oval window with resultant dampening of the perilymph, and (3) to support the articular surface of the head of the malleus. The function of the tensor of the tympanic membrane by action of the tensor tympani muscle.

The author then discusses the surgical classification of cases conforming with the hydrodynamic hypothesis. When the opening at the oval window end of the system is the cause of deafness, as in otosclerosis, with the fixed stapes sealing the oval window, the condition is called stapedia deafness. Obstruction to sound reaching the round window is termed hypotympanic deafness. To both of these groups must be added irreversible deafness with irreversible changes in the cochlear organ. The author supports the view that the round window is part of the sound pathway.

Hypotympanic deafness, which is responsible for a large group of cases of air conduction impairment, is caused mainly by chronic otorrhea and suppuration, the impairment being caused by granulations, polyps, and scar tissue around the region of the round window. The author operated on a number of patients with chronic suppuration and deafness, and each had a densely sclerotic mastoid process, the infection was confined to the attic. Considerable tissue, scars, etc., were found overlying the hypotympanum and thus sealing off the round window. In 27 cases the transtympanic technique was employed to clear the attic and hypotympanum. Eighty per cent of the patients exhibited a dry ear within 3 weeks, and the same percentage of patients had immediate postoperative improvement that amounted to almost normal hearing. Only 4 of these patients, however, maintained their hearing improvement, in the other cases new scar tissue may have formed. It is believed that we are on the verge of entering an era wherein operations directed toward this type of hearing loss may be carried out.

The author presents a number of diagrams to support his hypothesis. WILLIAM A. AERON, M.D.

Histopathologic Investigations on the Localization, Number, Activity, and Extent of Otosclerotic Foci. BENGT NYLÉN. *Uppsala läk fören förh*, 1949, 1: 1

Nylén has made an extensive investigation of 74 cases of otosclerosis and 3 other cases with pathological bone changes from the collection of temporal bones of F. R. Nager.

Preliminary to his investigation the author made a survey of the large series of histologically established cases of otosclerosis in the literature by writers acknowledged as authorities on this subject. From the survey, the following facts were pointed out.

In clinically established otosclerosis, nearly 100 per cent of the foci are located in the oval window region and are accompanied by ankylosis. In investigations of the frequency of otosclerosis in unselected material, this figure decreases considerably, and stapes ankylosis is less frequently encountered. Statistical calculations of the relation of age and sex to the incidence, and of the morbidity rate have not been possible because the series has been too small and the material lacked homogeneity. Because otosclerotic foci in other regions than those of the windows and stapes have apparently not been sought,

relatively little appears to be known about the localization of the lesions in the labyrinthine capsule outside of those regions. Thus, the author wished, by his investigation, to add to the present knowledge of the localization, number, activity, and extent of otosclerotic foci.

After uniform histological treatment and study of all his material the author presented his facts in case reports and in a complete tabulated form. In summary, the principal findings of the histological investigation were as follows:

- 1 Of 74 patients examined, with 121 temporal bones showing otosclerotic foci, 34 were females and 40 were males.

- 2 The localization of the otosclerotic processes was as follows:

In the window regions in 90 per cent of the cases, approximately 50 per cent of the cases with a localization at the oval window were associated with stapes ankylosis. The round window was involved in approximately 40 per cent of the entire material, the cochlear capsule in 35 per cent, the internal auditory canal region in 30 per cent, and the semicircular canal capsule in 15 per cent. Typical otosclerotic foci entirely outside of the labyrinthine bony capsule were rare, being found in only 2 instances.

- 3 A focus limited to only one of the regions mentioned in the previous paragraph was found in 55 per cent of the whole material. The process was confined to the stapedia region in 40 per cent and to the round window in 8 per cent of all cases. The 40 per cent involvement of the stapedia region is divided into 18 per cent with and 22 per cent without ankylosis of the stapes.

- 4 There was a higher proportional incidence of stapes ankylosis among the females, when the number of cases with foci at the oval window accompanied by stapes ankylosis was compared with the number of cases without the latter finding.

- 5 The pathological areas are usually symmetrically located in both temporal bones of a patient, except, obviously, in unilateral otosclerosis.

- 6 No difference in localization of foci appeared when the patients were divided into two age groups, that is, over or under 50 years of age.

- 7 A single focus occurred in approximately 65 per cent of the total number of bones, in the others there were two or more foci, those with more than three being rare.

- 8 On classifying the foci according to their degree of activity, active foci were found in 20 per cent of the cases, mixed in 50 per cent, and quiescent foci in the remainder. When several foci were present in the same bone or in the same individual they were usually of the same degree of activity. Mixed and quiescent areas were more common in the patients over 50 years of age.

- 9 The extent of the process varied from 0.4 mm to more than 20 mm, with no correlation between the extent, localization, and activity.

- 10 Diffuse otosclerosis usually involved the entire cochlear capsule, but the vestibule and even parts

SURGERY OF THE HEAD AND NECK

of the semicircular canal capsule were involved in approximately 10 per cent of the cases. Stapes ankylosis was considerably more common on comparing the material as a whole and the activity was extremely mixed.

11 The findings in the present investigation as well as in other recent investigations indicate that unilateral otosclerosis occurs in from 15 to 30 per cent of the cases collected for histological specimens.

12 Histologically, the foci in the oval window region were typical in extent. The round window was often occluded by the process. The lumina of the cochlea, the vestibule, and the semicircular canals were often compressed, particularly in cases of diffuse otosclerosis, whereas foci in the internal auditory canal do not appear to compress the lumen to any extent.

EUGENE L. DERLACKI, M.D.

Acoustic Function Before and After Operations for Otosclerosis

HARALD EWERTSEN *Arch Otolar*, Chic., 1949, 49: 393

This is the first of a series of 4 articles dealing essentially with the postoperative results following Popper's operation for otosclerosis and with acoustic function. The author made observations on the first 85 patients operated on in the ear department of the Sundby Hospital, Copenhagen, beginning November 8, 1946.

Of these 85 patients, 59 per cent complained preoperatively of paracusis, 1 patient, of 38 questioned, complained of diplacusis, and 89 per cent, of 70 questioned, complained of tinnitus. Hearing acuity was assessed on the basis of whisper and voice tests, audiometry, tuning forks, the monochord test, and the patient's own statement. Of the group capable of hearing voice at a distance of 10 cm or less, only 18 per cent obtained definite improvement, and this group must be regarded as unfit for fenestration. Of 30 patients operated on more than 6 months ago, 63 per cent showed "definitely improved" hearing. If the least fit group, i.e., those with hearing for speech less than 10 cm, are not included, 75 per cent of the patients obtained definite hearing improvement. This is shown in Table I.

TABLE I—RESULTS OF SPEECH TESTS OF 30 PATIENTS 6 TO 13 MONTHS AFTER FENESTRATION

per cent of the least fit group, are not included in the speech less than 10 cm, are not included in the patients obtained definite hearing improvement. This is shown in Table I

operation

TABLE I—RESULTS OF SPEECH TESTS OF 30 PATIENTS 6 TO 13 MONTHS AFTER FENESTRATION

Preoperative hearing distance	Patients	Ad aures to 0.10 M	Postoperative hearing distance						Safe improvement	
			0.10 M	0.50 M	1.2 M	4 M*	8 M	12 M		15 M or more
Ad aures to 0.10 M	10	5	1		1	1		1	2	4 of 10
0.10 M	9		1	1	1		1		5	7 of 9
0.30-1 M	5				1				2	3 of 5
1 m-3 M	3								1	2 of 3
4-60 M	1								1	1 of 1
800 M	2								2	2 of 2
Total	30									10 of 30 = 63%

*These figures indicate safe improvement.

*Bold face figures indicate safe improvement.

Fig 1 (Ewertsen) Air conduction values of 30 patients according to Fowler's test. The ordinate indicates the preoperative value in decibels, and the abscissa the postoperative value measured from 6 to 13 months after the operation. Eighteen of the 30 patients, i.e., 60 per cent, have obtained improved hearing.

The fistula, the author believes, closed in 13 per cent of 30 patients within 6 to 12 months postoperatively.

The air conduction values according to Fowler's test are given in Figure 1.

JOHN J. BALLENGER, M.D.

Popper's Operation for Otosclerosis

ROBERT LUND
Arch Otolar, Chic., 1949, 49: 380

Lund presents his experiences with 90 patients operated on for otosclerosis by his modification of Popper's original procedure. Popper's transtympanic operation differs from Lempert's transmastoid route

Fig 1 (Lund) A shows the "square on" presentation of the posterior wall of the external meatus and the drum B shows the incision made through the skin that lines the anterior wall of the bony meatus *a* and that made through the skin that lines the upper posterior part of the bony meatus *B*. The broken lines give the extent of the detachment of the margin of the tympanic membrane. The curved line I-II marks the incision of the anterior wall of the external meatus between the cartilaginous and the bony part.

principally by offering the surgeon a "square-on" approach to the site of election for the fenestra, namely, the "roof of the vestibule above the facial canal," according to the author.

Various modifications of Popper's original method are used by the author. The head of the patient is not placed in the side position but turned halfway upward. The author's incision is a curved one just anterior to the tragus rather than a straight one. After the anterior cartilaginous meatal wall is uncovered, a jaw lever is used to keep the mouth open (and thus provide more room), and the entire anterior bony wall (the tympanic plate) is removed.

Popper sacrifices the cutaneous lining of the tympanic plate, but the author elevates and preserves the skin and from it forms a skin flap, as shown in Figure 1, to be used in covering the vestibular fenestra. Entry to the attic is then gained by drilling with a 2 mm burr, as shown in Figure 2, and then removing the bony wall with chisel and punch. The incus is then easily removed through this opening but the head of the malleus is not disturbed.

The fenestra, after Lund's modification, is made in the vestibule just above the facial canal. After removal of the periosteal layer of the cupola an elongated hole is made in the most prominent part of the cupola. During this process, the field is under continuous irrigation with Ringer's solution.

After the fenestration, the tympanomeatal flap is placed over the fenestra and kept in place by tamp-

Fig 2 (Lund) A shows the pars flaccida of the tympanic membrane plus the meatal flap reflected forward over the tympanic membrane. The crus longum incus is seen in the depth. A hole is drilled in the lateral attic wall over the vestibular space *a*. The "bridge" *B* is chiseled off. B shows the hole of the lateral attic wall widened, the incus presenting. A relief of the facial canal is seen in the depth.

ing loosely with gauze. The operation is performed under general anesthesia. The patients are given sulfanilamide preoperatively and postoperatively and penicillin postoperatively.

The author believes that Popper's transtympanic approach has an important advantage over the transmastoid approach in that the "square on" view makes the operative technique easier. Thus, the operative trauma is less. The author's modification of Popper's method involves mainly the suggestion of an inverted U-shaped meatal flap, the width corresponding to the attic wall. He gives a summary of his operative mishaps. JOHN J. BALLENGER, M.D.

Transtympanic Approach and Fenestration. The Current Technique. OTTO POPPER *Arch Otolaryngol*, Chic, 1949, 49: 350.

The author discusses his transtympanic approach in operations on the middle ear. It is ideal for the performance of atticotomy if the mastoid process is sclerotic and the infection is confined to the atticotomy region as an alternative procedure to the radical mastoidectomy. It is also a dual procedure, as it can be used in the fenestration operation, it is a transtympanic approach followed by the Lempert fenestration.

The author discusses in detail the advantages of his procedure over that of the Lempert technique. It is a difficult operation to learn, he admits, and should be practiced on cadavers even if the student is an expert with the Lempert procedure. The position of the patient at operation, and the illumination and magnification of the operative field are also discussed.

The author discusses a series of 200 cases and the difficulties in evaluating the results to date because of the time element and the newness of the procedure. He admits that his record is not as impressive as some other previously published studies, but he

SURGERY OF THE HEAD AND NECK

hopes that with more experience, and with other surgeons using the transtympanic approach, the records of achievement will be equalled.

In conclusion, the author gives a somewhat detailed description of the operative technique for the transtympanic approach. The article contains diagrams and drawings showing the different stages of the operation.

WILLIAM A. AHROON, M.D.

NOSE AND SINUSES

Benign Cysts of the Superior Maxilla with Special Reference to Cysts of the Maxillary Sinus. Clinicopathologic Study of 30 Cases. LELAND R. HOUSE. *Arch Otolaryngol*, Chic., 1948, 48, 301.

The author discusses cysts of the superior maxilla and reviews 48 selected cases from the White Memorial Hospital, Los Angeles, California. These cysts occur more frequently than is generally believed. In 27 cases of this series of 48 selected cases radical surgical procedures were performed on the maxillary sinus for some type of cyst, in 24 of these the cyst was found in the maxillary sinus, and in 3 it was found in the bony palate adjacent to the sinus.

There are various classifications of these cysts, but the following are those of the author:

- 1 Cysts of nonodontal origin
 - a Retention cysts (secreting cysts)
 - b Nonsecreting cysts of the nasal mucosa
 - c Mucocoele
 - d Traumatic bone cysts
- 2 Cysts of dental origin
 - a Follicular (dentigerous) cysts
 - b Radicular (root) cysts
- 3 Cysts of nonodontal origin developing from defects in embryonic life
 - a Median anterior maxillary cysts
 - b Facial cleft cysts

The author discusses the pathology, etiology, findings at examination, and the diagnosis of these various types of cysts in some detail. He also gives short case presentations of each type of cyst. These types are also illustrated by photographs and photomicrographs.

MOUTH

Cleft Lip and Palate. Some Technical Procedures Used in Its Treatment, with Especial Reference to Closure of Complete Cleft of the Anterior Half of the Palate. FRED Z. HAVENS. *Arch Otolaryngol*, Chic., 1948, 48, 9.

Procedures for the repair of harelip have been thoroughly described and discussed by numerous authors. For the single harelip the Mirault operation is a most excellent procedure and is applicable in a large percentage of cases. It may be necessary, however, to make modifications in order to cope with special problems. Occasionally the Rose operation is preferable, especially in cases of incomplete harelip. In the management of the accompanying nasal deformity, emphasis is to be laid on the necessity of

building a good floor for the nostril, of freeing the tissues widely so that the nose comes into proper relationship to the face as a whole and, finally, of making the necessary dissections in order to mobilize the alar cartilages so that they can be brought into as nearly normal position as possible.

For bilateral complete harelip, the Thompson operation combined with the procedure advanced by Veau for closure of the alveolar and anterior palatal clefts has given excellent results.

For the repair of those clefts which involve only the soft palate or the soft palate and the posterior half to two-thirds of the hard palate, the author has employed the Wardill type of operation with gratifying results.

He is of the opinion that it is important to free the soft tissue from the medial surface of the internal pterygoid plate above and behind the hamular process after this has been disconnected. The procedure which he follows is described in the complete article.

Repair of the incomplete cleft of the palate usually is deferred until the patient is between 14 and 16 months of age.

For the complete cleft of the palate, either single or bilateral, the author prefers the Veau type of operation if the cleft involves the anterior part of the palate and the alveolar process.

In cases of single palatal cleft and associated single harelip, the Veau type of closure of the anterior half of the palate and of the alveolar process is combined in a single stage with a Mirault type of repair of the harelip.

In cases of bilateral complete cleft palate and bilateral harelip, the bilateral Veau operation and the bilateral repair of the harelip sometimes can be done as a single operation, or the anterior part of the palate and the lip can be repaired on one side only at one time, and the same operation done on the other side after an interval of from 10 days to 2 weeks. Often, the decision whether to use the single stage or the two stage method is not made until the defect of one side has been repaired. If the operation has proceeded smoothly thus far and if the child is taking the anesthetic well and is in good condition, one can proceed with the repair of the defect on the other side, otherwise, it is better to defer the remainder of the repair until later.

In cases of bilateral cleft of the palate and lip, the Thompson method of repair of the lip is preferred. When the premaxilla projects badly, it usually can be forced back by digital pressure so that the lip can be closed, and only rarely is it necessary to section the vomer. If section of the vomer is necessary, simply dividing it so that the anterior segment can slide back alongside the posterior segment is preferable to removing a portion of it.

The author is fully aware that criticism has been made of the Thompson type of operation for double harelip. However, it is not to be expected that this severe deformity can be corrected satisfactorily by a single operation in infancy. Further plastic operations are needed almost invariably.

This tumor, often diagnosed as a malignant neoplasm, presents itself as an immovable, hard, and smooth or lobulated tumor of one of the salivary glands, most often the submaxillary. Its growth is slow and painless, with fixation to the surrounding tissues, such as the buccal mucosa, by solid adhesions. No abnormality of the salivary duct orifice is noted.

The diagnosis is made by histologic examination, after total excision, and the principal features of the histologic picture are abundant fibrous connective tissue separating the acini and enclosing various-sized sections of glandular parenchyma, infiltration of polymorphonuclear leucocytes and plasma cells, destruction of glandular parenchyma, and thickening of the lumina of the ducts.

After reviewing the opinions of other writers the author concludes that the etiology, although as yet unclear, is not related to the common pyogenic organisms, since the inflammatory process is not characterized by tissue softening, necrosis, and purulence.

The treatment of choice is excision of the tumor, and no recurrence has ever been reported.

PHARYNX

A Clinical and Pathologic Study of Tonsil Tags

J. OLIVER GOOCH and HAROLD I. LILLIE *Ann Otol Rhinol*, 1948, 57, 957

The authors' study of cases of tonsil tags at the Mayo Clinic and in the literature on this subject reveals that the physiology of the tonsil is poorly understood. This study also indicates that the presence of tonsil tags is difficult to demonstrate in many instances, and reliance should be placed on qualified otolaryngologists for this examination.

The common associated signs and symptoms of 171 patients who underwent operation for the removal of tonsil tags at the clinic, in order of frequency, were (1) sore throat, (2) pain in the joints, (3) cervical adenitis, (4) lassitude, (5) loss of weight, and (6) fever. The common associated conditions diagnosed in patients undergoing operation for removal of tonsil tags, in order of frequency, were (1) arthritis, (2) fibrositis, (3) chronic heart disease, (4) chronic disease of the middle ear, (5) chronic renal disease, (6) affections of the eyes, and (7) asthma.

The cause of tonsil tags is incomplete removal of the tonsils. Complete removal can be accomplished only when the thickened capsule is removed by sharp dissection.

The average tonsil tag can be described compositely as a bit of tonsil tissue of varying size covered by stratified squamous epithelium which also lines the crypts. The crypts contain increased amounts of keratin, cellular debris, and leucocytes. Stasis, as a result of induration, is present in the crypts, a condition which provides suitable soil for infection. Ulceration of the epithelium lining the crypt is frequent. The lymphoid elements continue to be arranged in

characteristic pattern and germinal centers remain when a sufficient amount of the lymphoid tissue is present. When the lymphoid tissue is of such a scant amount that only nests of it without germinal centers are seen, the stroma of the gland shows considerable increase in fibrous connective tissue, particularly in the subepithelial area and in the trabeculae in which the blood vessels course. The capsule is thickened and may contain isolated bits of lymphoid tissue or cystic areas of varying size. The entire gland is indurated and inelastic when compared to a normal whole tonsil. Tonsil tags were found to be more dangerous from a standpoint of infection than are whole tonsils. Diathermy tags studied presented the same pathologic qualities as those of operative tags but in greater degree.

NECK

Nontoxic Nodular Goiters GEORGE CRILE, JR., and W. S. DEMPSEY *J. Am. Med. Ass.*, 1949, 139, 1247

The present study was undertaken with a view to determining whether the routine removal of soft, nontoxic nodular enlargements of the thyroid is warranted, as is that of firm nontoxic adenomas. Between 1937 and 1946, 30 malignant tumors were encountered in a series of 768 thyroidectomies, an incidence of 3.9 per cent. Of 274 nontoxic nodular goiters removed surgically, 10.9 per cent proved to be malignant, as did 24.5 per cent of 98 cases of nontoxic solitary tumors. The incidence of malignancy in 537 nodular goiters, with or without hyperthyroidism, was found to be 5.6 per cent. The correct diagnosis was made or suspected prior to operation in over 90 per cent of the patients presenting malignancy.

It was pointed out that the figures obtained in this study could be interpreted as indicating that (a) over 3 per cent of nontoxic nodules of the thyroid are undiagnosed malignant tumors, or (b) there is only 1 chance in 6,675 that removal of a nontoxic solitary nodule in the thyroid will give protection against death from carcinoma of the thyroid. Emphasis was also placed on the pitfalls inherent in statistical determinations of the incidence of carcinoma of the thyroid in nodular goiter. It was believed that the high incidence of carcinoma reported by surgeons was due principally to the selectivity of cases for surgery, the obviously benign nodules being screened out by the patient or internist.

The authors came to the conclusion that it was best to base indications for removal of nodular goiters on clinical judgment rather than on statistical surveys. The pertinent concern, it was reasoned, was not motivated by the question of subsequent malignant transformation of an adenoma as much as by the possibility that carcinoma existed at the time of examination.

The authors urged that solitary thyroid adenomas be viewed with suspicion, irrespective of the age of the patient, particularly in cases in which the tumor is enlarging, discrete and firm, and of a different

consistency from the rest of the gland. The removal of large adenomas for cosmetic reasons was also recommended. However, it was felt that soft involutary nodules which were multiple, inconspicuous, and asymptomatic, and which were not enlarging in size could be disregarded.

DAVID H. LYNN, M.D.

Carcinoma of the Thyroid Gland WILLIAM E. HOWES and MERRILL N. FOOTE *Radiology*, 1949, 52: 541

The authors have studied 40 proved cases of carcinoma of the thyroid in patients admitted to the Brooklyn Cancer Institute. Of these, 33 were females and 7 were males. The average age of the patients was 55 years. The lesions were classified microscopically as anaplastic carcinomas, papillary adenocarcinomas, adenocarcinomas (including Hürthle-cell adenocarcinomas), squamous cell carcinomas, and unclassified carcinomas.

Adenocarcinomas, presumably arising in adenomas, were found in the largest group in this series. Although such tumors were prone to metastasize early via the blood stream, often before the parent neoplasm was recognizable, more than 50 per cent of the patients survived 5 years or longer. The outcome was less satisfactory in the 4 remaining groups,

only 6 other patients in the entire series surviving. The high percentage of survivals among the patients with adenocarcinoma is attributed to radiosensitivity of the lesion, the slow growth of the parent tumor and its metastases, and the unusual tolerance of patients to this neoplasm.

Medullary or anaplastic carcinomas were found to grow rapidly and metastasize early, seldom to bone. They were inclined to be radiosensitive but not radiocurative. Metastases of papillary carcinoma frequently overshadowed and masked the primary tumor and took place early via the cervical lymphatic chains. However, metastasis was seldom widespread. Squamous-cell carcinoma and sarcoma of the thyroid are extremely rare, only 1 case of the former type being encountered.

In general, the prognosis continues to remain poor if the presence of carcinoma of the thyroid is sufficiently evident prior to operation to warrant this diagnosis. The most successful results are achieved when the neoplasm is localized within an adenoma. Surgical treatment combined with irradiation appears to have improved the life expectancy in the more advanced cases. At least 2 patients appear to have obtained symptomatic improvement from the use of radioactive iodine (I^{131}).

DAVID H. LYNN, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS, CRANIAL NERVES

Abscess of the Brain JOHN MARTIN and LOYAL DAVIS
Q Bull Northwest Univ M School, 1949, 23 64

Since the advent of chemotherapy and antibiotics the course of infection in various parts of the body has been strikingly altered. Acute cerebritis and brain abscess are no exceptions, and thus the surgical problems and clinical pictures have been considerably changed. This article points out the problems now involved in the management of cases with localized infection of the brain. The material consists of 105 patients with a diagnosis of brain abscess, in 89 of whom the diagnosis was verified, in 16 it was not, but most of the latter were patients treated intensively by chemotherapy and antibiotics. The authors had experience with a large number of brain abscesses due to open wounds incurred in military service.

The pathology of brain abscess is adequately discussed with reference to the usual sources of origin. The result of infection in the brain is reviewed, with illustrations, from the swelling of the white matter through areas of liquefaction to the encapsulated abscess. Abscess of the brain is still difficult to localize for some of the methods usually employed in expanding lesions are not acceptable and others are not reliable. Encephalography and even ventriculography may be dangerous and electroencephalography is not specific for abscess as opposed to swelling and softening. Neurological examination is, of course, the most reliable guide but this may fail. Further, since the use of intensive chemotherapy, encephalograms have been normal in patients strongly suspected of having an abscess which eventually must have cleared up under intensive modern treatment.

The surgical problem has changed with recent methods. Fewer patients are seen with brain abscess and far less of these come to operation. Under intensive treatment with penicillin and sulfadiazine, fewer abscesses go on to capsule formation and so fewer abscesses are tapped or are totally removed. Some years ago abscesses were allowed to form capsules and were either tapped as often as necessary or they were completely extirpated. Tapping may still be necessary and subtemporal decompression may be required to counteract the swelling of the brain, but the aftermath has many drawbacks. Many patients have residual neurological defects such as some contralateral weakness, aphasia, or Jacksonian seizures. The mortality rate is now much lower and many abscesses may be cured as far as their infectious component is concerned but apparently, in the brain, as elsewhere in the body, this cannot be done without scar formation and destruction of substance. ADRIEN VER BRUGGEN, M D

SPINAL CORD AND ITS COVERINGS

The Cause of Spinal Paralyzes with Special Attention to Factors Responsible for Compression
(Zur Aetiologie der spinalen Laehmungen mit besonderer Beruecksichtigung der Kompressionsnoxen)
ROBERT H. VON MURALT *Helvet chir acta*, 1949, 16 3

A review of 104 patients with extramedullary and 17 with intramedullary compression of the spinal cord who were operated on during a 10 year period led the author to the following conclusions:

A subdivision of intravertebral processes into intramedullary and extramedullary types is of practical importance from the therapeutic point of view.

All factors responsible for compression of the spinal cord may be divided into mechanical, infectious, anoxic, idiopathic, and congenital.

Metastases, meningitic processes, injuries, kyphoscoliosis, and Paget's disease may serve as examples of mechanical factors. Suppurative or tuberculous meningomyelitis, mycoses, and acute anterior poliomyelitis are representatives of infectious processes. Blood or air emboli may cause anoxemia. Examples of an idiopathic degeneration are spastic spinal paralysis or amyotrophic lateral sclerosis. Congenital malformations are represented by syringomyelia or hydromyelia.

One-third of all the intramedullary tumors were malignant.

Among the benign tumors there were 34 neurinomas, 25 meningiomas, and 9 other types.

The author calls attention to the fact that compression of the spinal cord at any level is able to produce a flaccid paralysis.

Compression of the spinal cord may be mistaken for arachnoiditis, Elsberg's disease, thickened ligamentum flavum, kyphosis, and spinal varicosities.

Hereditary factors have not been sufficiently elucidated but seem to be of minor importance.

The rôle of trauma must be denied in the majority of cases.

Untoward effects of spinal puncture can usually be avoided by strict observance of all technical rules and the employment of a fine needle.

Myelography is harmless if a small dose of a water soluble contrast medium is used.

JOSEPH K. NARAT, M D

PERIPHERAL NERVES

Vasomotor Changes in Peripheral Nerve Injuries
C. A. R. SCHULENBURG *Surgery*, 1949, 25 191

An interesting study is presented of the changes in skin temperature produced by degenerating or regenerating peripheral nerves in various periods after injury and repair. The skin temperatures were measured by a "sensitive instrument employing a light-

consistency from the rest of the gland. The removal of large adenomas for cosmetic reasons was also recommended. However, it was felt that soft involutary nodules which were multiple, inconspicuous, and asymptomatic, and which were not enlarging in size could be disregarded.

PERIPHERAL NERVES

Vasomotor Changes in Peripheral Nerve Injuries
C A R. SCHULENBURG *Surgery*, 1949, 25 191

An interesting study is presented of the changes in skin temperature produced by degenerating or regenerating peripheral nerves in various periods after injury and repair. The skin temperatures were measured by a "sensitive instrument employing a light-

beam galvanometer." After section of a peripheral nerve the denervated skin passes through a temporary warm phase of initial vasodilatation lasting approximately 3 weeks, and a more permanent cold phase in which the temperature corresponds mostly to that of the environment. The author considers that the warm phase is caused by interruption of the vasoconstrictor sympathetic fibers within the peripheral nerve.

Various factors are responsible for the change from the warm phase to the cold phase, such as the lowering of the local metabolism of inactive or inert tissue. Division of postganglionic sympathetic fibers in the peripheral nerve sensitizes the denervated vessels to circulating adrenalin. This drug was found to produce significant falls of temperature in totally denervated areas, slight but definite falls in partially innervated areas, and only a slight insignificant fall in normal areas. The axonal vasodilatation of Lewis (histamine flare) occurring in response to minor trauma disappears after nerve degeneration is complete, but is present during the degenerating and regenerating process. The reduction of the total blood flow to the entire limb as a response to cold environment was thought to be not as important as the local environmental temperature itself. The prolonged effect of short exposure of the denervated skin to cold temperature was thought to be due to local effect on the blood vessel walls. A thickening of the intima and the media, with interruption of the internal elastic lamina, was found in digital vessels in cases which came to amputation.

Plethysmographic studies showed interesting changes after reflex warming of the involved extremity, which were characteristic of nerve regeneration.

GEORGE PERRET, M.D.

Open Wounds of the Brachial Plexus DONAL M. BROOKS *J Bone Surg*, 1949, 31-B 17

In 42 of 820 peripheral nerve injuries due to penetrating wounds, the brachial plexus was involved. In order to compare the results, the author adopted the following method of grouping the injuries.

Group 1 consisted of lesions of the roots and trunk of the fifth and sixth cervical nerves, Group 2 consisted of lesions of the posterior cord, and Group 3 was made up of lesions of the eighth cervical nerve, the first thoracic, and the medial cord.

The object of the study was to answer pertinent questions regarding the findings, results, and the advisability of exploration of the brachial plexus in injuries due to open wounds. All patients were treated by electrical stimulation of the paralyzed muscles, and observations are recorded for at least 2 years following injury.

The brachial plexus was explored in 22 patients. In only four instances, however, was interruption of continuity of the nerves found, in contrast to the frequency of division of nerves in more distal injuries under war conditions. It was not considered justifiable to resect a lesion in continuity, and there was no evidence that neurolysis influenced recovery

in any instance encountered in the 22 explorations, although the scarring was severe. The findings at exploration are classified, and correlation between the operative findings and the prognosis is not considered precise. Results of repair in 3 cases of nerve severance were discouraging.

The recovery of patients in Group 1 was good, in Group 2, fair, and in Group 3, poor. Five patients presented Horner's syndrome, and in 11 patients the brachial plexus paralysis was associated with injury to a main vessel. Analysis of the results is clarified by the inclusion of case histories in well planned tables. The author concludes that the routine exploration of open wounds of the brachial plexus is not justified.

JOHN L. BELL, M.D.

Modern History of Peripheral Nerve Surgery BARNES WOODHALL. *J Am M Ass*, 1949, 139 564.

The recent war caused a tremendous amount of peripheral nerve surgery to be done and provided a stimulus for research on the regeneration of nerves in the human being. Some 15,000 peripheral nerve operations were performed and a Peripheral Nerve Registry of World War II was established. By the end of hostilities about 7,000 nerve sutures were registered and follow-up clinics have been established for veterans. These should eventually add to the experience in this field and lead to some application in civilian practice.

Suture material was carefully considered and, finally, tantalum wire 0.003 inch in diameter was found useful not only because it was inert in the tissues, but also because the suture line could be reviewed roentgenologically. Fine silk was easier to handle in some cases of small nerve repair. Plasma glue was useful as an auxiliary when there was no tension on the suture line. Nerve grafting, and especially cable grafting, was said to be of help when there were nerve defects that could not otherwise be bridged.

Causalgia, whatever its etiology, was almost universally relieved by chemical or surgical interruption of the appropriate sympathetic nerve fibers. This distressing complication occurs in about 3 per cent of nerve injuries.

The proper time for suture has been debated but it appears that the definitive time is from 3 to 6 weeks after the initial trauma. Normal wound healing occurred in 98 per cent of the cases and failure of the suture line in only 5 per cent as compared to 22.4 per cent following immediate nerve suture. Operation is performed best under relatively normal conditions both as far as the patient and the surgeon are concerned.

Evaluation of Treatment of Hypertension WINCHELL MCKENDREE CRAIG *J Am M Ass*, 1949, 139 1239

Essential hypertension, similar to all disease entities of which the causes are obscure, has a tendency

to progress as time and age advance. It requires careful and frequent observation, and treatment should be instituted before more severe stages of the disease develop. Abnormal elevation of the blood pressure may persist for years in a minimal degree without producing symptoms or disability, and more severe elevation of the blood pressure may respond to medical management and remain under control without being disabling or showing evidence of progression. The problem confronting the medical profession today is the control of progressive hypertension, and the prevention of irreparable damage to the various structures of the body.

Not much is known about the mechanism of elevation of the blood pressure in essential hypertension. Three factors are responsible for maintaining normal blood pressure, and derangement of any one of these may cause a change in the blood pressure. The cardiac output, the volume or viscosity of the blood, and the resistance to the flow of the blood through the peripheral arterial system determine the blood pressure. Cardiac output or viscosity of the blood is not altered in essential hypertension, but the caliber of the peripheral vessels is decreased. The decrease in diameter of the peripheral vessels is attributable to (1) a condition inherent in the arterioles and (2) an abnormal reaction of the arterioles to vasomotor stimuli.

There is a large hereditary factor in essential hypertension. Little therapeutic interest has been centered on early or potential hypertension in spite of definite evidence that heredity plays a part in the etiology, that hyper-reactive children have been found, and that a recent report from one of our leading medical schools revealed that 20 per cent of the students were found to have arteriosclerosis.

Treatment may be classified as expectant, physiologic, and palliative. Expectant treatment con-

sists of (1) determining whether the patient is a hyper-reactor and has early hypertension, (2) instruction as to the harmful effects of nicotine and emotional stress, and (3) education in the proper methods of living.

The physiologic treatment comprises both medical and surgical measures and is indicated in the early stages of the disease before irreversible changes have taken place in the vascular and organic tissues of the body. This type of therapy is instituted to arrest the progress of the disease. The medical treatment consists of diets and drug therapy. The surgical treatment consists of operations upon the sympathetic nervous system to relieve vasomotor spasm of the vessels of the splanchnic region, abdomen, and lower extremities.

Palliative treatment consists primarily of surgical measures. Its objective is to relieve the incapacitating symptoms of the later stage of the disease without arresting the progress of the condition or lowering the blood pressure.

The author's observation is that less radical operations might be followed by more permanent results if instituted earlier in the course of the disease. If the less radical operations are not entirely successful or if the results prove temporary, the more radical procedures can then be done.

Instead of an attempt to evaluate surgical results by classification of the condition of the patients post-operatively, it would seem that a more rational basis would be the assigning of the hypertension of a patient to the correct individual group preoperatively. This, together with the prognoses associated with the several groups of hypertension, would form a background for evaluation.

The author has presented a report of 4 cases in the complete paper and has enlarged on each of the three types of treatment for hypertension.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

The Operative Treatment of Pectus Excavatum

MARK M. RAVITCH *Ann Surg*, 1949, 129 429

Pectus excavatum is a deformity of the thorax which is marked by a sharp posterior curve of the body of the sternum—deepest in the inferior portion. The lower cartilages bend inward and the sternum moves posteriorly on inspiration. The deformity is usually progressive from birth. Physiologic disturbances of the thoracic viscera may occur. The mechanism of the deformity is uncertain. It may be due to a short central tendon. At operation a tough fascial band, tensely stretched between linea alba and sternum, is usually found. On section of this band the sternum may be elevated.

Operation is undertaken to correct the existing deformity and to prevent its progression. Indications for operation are (1) cosmetic, (2) orthopedic, and (3) physiologic. In the procedure described, the xiphisternal articulation and substernal ligament are divided and all the deformed costal cartilages are dissected. A transverse cuneiform osteotomy is performed at the sternomanubrial junction and the position is maintained by braided silk sutures. No traction is used. The defect from excision of the cartilages is allowed to remain.

The author points out that early operation is important as a prophylaxis against progression of symptoms and signs. He has treated 8 children ranging in age from 22 months to 10 years. In 7 children there were no complications and the results were excellent. One child died of a fulminating wound infection.

ROBERT E. FLORER, M.D.

Mammoplasty for Pendulous Breasts

G. AUFRICHT *Plast Reconstr Surg*, 1949, 4 13

Any reconstructive operation on a woman's breast is a major problem in technique and esthetics. Certain precautions must be observed: (1) fixation landmarks should be considered in relation to the thorax, (2) allowance should be made for the elasticity of the skin and the effect of breast weight on it, (3) measurements of both breasts should be made under similar conditions, to produce symmetry.

From the surgical point of view, all breast tissues are well vascularized and there is sufficient blood supply from any direction to nourish the corresponding breast tissue. It should be treated as in the preparation of a skin flap, providing a sufficient nourishing pedicle to the remaining gland, and leaving a broad central axis of tissue intact to protect the areola and nipple.

The esthetic aims are normal size, form, position, symmetry, and inconspicuous scarring. An attempt should be made to form a gently pendant, mature breast rather than a virginal one, as it is more normal in appearance, longer lasting, and the scars are less

conspicuous. A tight skin brassiere must be made to maintain this effect.

There are two approaches to mammaplastic operations: (1) improvised (without presurgical mensuration), and (2) presurgically planned—(a) visual empiric or (b) geometric.

The visual empiric planning is as follows. The new nipple site is selected visually with the patient standing erect with arms relaxed, and then marked. The width of the breast is measured about 1 or 1½ inches above the planned nipple site, and the width bisected. The central point is connected with the actual nipple, and the point at which this bisects the planned nipple level will be the site of the new nipple. The breast is then pushed forcibly to one side and the point in the submammary fold below the nipple site is connected with a straight line to the new nipple site. The breast is then pressed in the opposite direction and the same points connected. The skin between these lines is the vertical sector to be removed. A transverse segment must be removed at the lower aspect of the breast to correct the redundancy. This is done by measuring the distance between the new nipple site to the submammary fold on the vertical lines and excising the medial and lateral triangles below these points, taking care not to extend the apex of the inner triangle beyond the lateral sternal line to insure inconspicuous scarring.

The normal breast can be considered as a geometric body, a hemisphere, or a cone. As such it has geometric components, namely, circumference, diameter, radius and axis, and can be used to reconstruct a pendulous breast.

The normal or reconstructed breast should be placed between the lateral sternal and preaxillary lines and between the submammary fold and the lower border of the third rib.

The diameter of the breast should be equal in the vertical and transverse planes between the boundaries indicated above. If not, the sums are added together and divided by 2, to get the mean diameter. Similarly the procedure is carried out on the opposite breast. If there is a great difference between the mean diameters of the two breasts, the two are added together and divided by 2, the resultant sum being acceptable for the diameter of each breast. The thickness of the breast is measured from the chest wall to the summit of the breast. A quadrangle is then drawn on a piece of paper, the long side equal to the diameter and the short side equal to the thickness of the breast. The quadrangle is divided into three equal parts and a diagonal is drawn through the first two-thirds and another in the opposite direction through the last third. These diagonals represent the silhouette of the breast. The long diagonal is projected on the mammillary line from the lower border of the third rib and the lower end indicates the new nipple site.

SURGERY OF THE THORAX

With the aid of the diameter, the circumference of the required skin flap can be established by the use of the mathematical formula π , which denotes the ratio of the circumference of a circle to its diameter (3 1416)

The requisite flap is fashioned from that available by measuring the width of the hypertrophic breast, multiplying by 3, and measuring this circumference on a circular flexible metal tape, placing the zero mark at the upper limit of the new breast (third rib), the mid-marker at the opposite pole on the mammary line, the skin included in the circle being the amount available. Now half distance points of the circumference of the planned breast are marked on the large circle from the zero point, forming an inverted V. The shorter diagonal of the quadrangle connected with the new nipple site, forming an inverted V. The paper pattern is then measured on this V from the nipple site. The redundant skin to be excised is that between the inverted V and down to the submammary fold. To measure the amount of breast tissue proper, the diameter of the planned breast is used, subtracting 2 cm for the thickness of the skin covering, figuring the new circumference, and measuring this amount on the periphery of the hypertrophied breast, removing the residual sector at whatever location is desired by the surgeon, but excising not closer than 2.5 to 3 cm to the center of the circle to preserve the areola. This discrepancy in geometric planning may be compensated by removing an additional 1.5 cm from the periphery and making the circumference of the planned skin brassiere 1.5 cm longer.

The areola is similarly reduced in circumference in proportion.

When the reconstructed breast is affixed in its proper position, the areola is anchored in position, and, as a control measure before excision, the skin is approximated with towel clips along the planned lines and any necessary adjustment of the skin brassiere can be made before the excess skin is excised.

Fine silk sutures are used for closure of the skin margins, with drains at medial and lateral aspects of each breast, and a dressing of fluffed gauze and a snug binder is applied.

LOUIS T BYARS, M D

Some Enigmas Associated with the Genesis of Mammary Cancer in Mice

JOHN J BITTNER

Cancer Res, 1948, 8 625

The interpretation of data on the genesis of mammary cancer in mice in which the disease results from the interaction of several causative factors is becoming more difficult as shown by a review of the results of various experiments.

Because of the isolation of sublines within inbred strains of mice, and the possible influence of the altered genetic constitutions, as well as of environmental factors, upon the final results, controls should be maintained for each experimental series.

The physiological response of animals of various stocks following castration has been found to be

dependent upon the genetic constitution of the animals. In several strains an association has been found between adrenal hyperplasia and estrogenic stimulation of the secondary sex organs, as well as with the inherited hormonal influence. The possibility of other inherited hormonal factors is considered and discussed.

As the basis for further research, it is suggested that the role of the mammary tumor milk agent in the genesis of mammary cancer in mice may be to alter the hormone metabolism with the production of more "carcinogenic" hormones.

TRACHEA, LUNGS, AND PLEURA

Tracheobronchial Tuberculosis in General and Its Connection with Pulmonary Surgery

P M

STEINER. *J internat chir thor*, 1949, 1 7

The author gives a description of the various forms of tuberculous alteration of the bronchi, classing them according to the 3 stages of the evolution of tuberculosis.

Tertiary tuberculosis is divided into two kinds of alterations: those secondary to common phthisis, aggravating evolution and prognosis, and the seemingly primary alterations situated in the large bronchi and resulting in severe scarring stenosis. The latter seem to be a good indication for pneumonectomy when the disease is not too advanced and the patients are well selected.

JOHN J MALONEY, M D

An Analysis of Variations of the Segmental Bronchi of the Right Lower Lobe of 50 Injected Lungs

FRANKLIN R SMITH and EDWARD A. BOYDEN J
Thorac Surg, 1949, 18 195

Notwithstanding the general acceptance in this country of the Jackson-Huber terminology of the bronchopulmonary segments, and in the British Empire of the somewhat differently named but corresponding zones, there seems not to have been made, as yet, a statistical study of the variations of the lower lobe segments. Brock discussed these from the standpoint of the varying amount of territory a given segment can cover and published excellent figures of some of these injected specimens. However, there still remains the task of analyzing variations in the light of an empirically established prevailing pattern, that is, of determining the typical surface area of a segment and then noting how often, and by what other bronchi, this is supplied in whole or in part. Such an analysis would seem to be a necessary preliminary to accurate localization of lesions of the lung and to surgical resection of its segments.

The present study is restricted to the segments of the right lower lobe.

The terminology employed in designating the bronchopulmonary segments is that proposed by Jackson and Huber (1943). The numerical designation of branches is that devised by Boyden (1945).

The distribution and arrangement of the segmental bronchi of the right lower lobe have been studied in 50 fresh lungs by the following methods (1) the successive injection of the principal bronchi by differently colored gelatin masses, (2) the accurate sketching of each injected lobe, to record the surface distribution of the bronchi on interlobar, costal, and diaphragmatic surfaces, and (3) the dissection of each lobe, to verify the distribution of bronchi and to ascertain their mode of branching.

From these data it has been possible to establish the prevailing pattern empirically, and to analyze the principal variations in the light of that knowledge.

As viewed from the interlobar surface the right lower lobe may be divided into superior and basal zones, the line of separation usually falling at the interfissural crest. Posteriorly, an interpolated, "subsuperior" zone can be demonstrated between superior and basal segments in 100 per cent of specimens (*vide infra*).

Since the superior segment is resectable, it is important to know its extent. Prevailing, it "caps" the basal segments horizontally, but in 38 per cent of specimens it is obliquely fitted to the basal segments. Usually (in 78 per cent), it occupies the upper half of the lobe, but it may occupy two-thirds of the lobe (8 per cent) or only one-third (14 per cent). On the paravertebral surface it may extend two-thirds (or more) of the way to the diaphragm (30 per cent of specimens).

The superior segmental bronchus (B^6) has three constant ram— a medial (B^6a), a superior (B^6b), and a lateral ramus (B^6c)—but it rarely trifurcates (6 per cent), the prevailing pattern (86 per cent) being a bifurcation into B^6a+b and B^6c . On the interlobar surface the superior segment is usually fused to a greater or lesser degree with the right upper lobe, and in 5 of 11 consecutive specimens examined for this purpose a branch of B^6b was observed to supply the adjacent portion of the right upper lobe. This may explain how consolidation of the lower lobe, in lobar pneumonia, may extend into the adjoining area of the upper lobe.

The subsuperior zone is a constant posterior zone interpolated between superior and basal segments. In this series of dissections it has been identified in 100 per cent of specimens, as contrasted with Brock's identification of only 48 per cent in a series of bronchograms. It is supplied by one or more posterior bronchi of inconstant origin. These arise from levels 1.5 to 5 cm below the orifice of the superior bronchus (B^6). For this reason, the bronchi supplying this zone have been indicated by the noncommittal designation, " B^* " (Boyden, 1945).

In general the principal levels of origin correspond to Aeby's dorsal bronchi, d_2 and d_3 (the first dorsal being the superior bronchus, B^6). That posterior bronchus which arises from Level 2 (that is, from the common stem of B^8 , 9 and 10 or B^{9+10}) is designated the "subsuperior proper," B^* . That posterior bronchus which arises from Level 3 (that is, from the

trunk of B^{10}) is designated the "accessory subsuperior," $BX^*(10)$.

In about one-half of the specimens (48 per cent), the subsuperior bronchi arise from both levels, and range in number from two to four. In the remaining one-half (52 per cent), there is only one subsuperior bronchus—more commonly BX^* (38 per cent), as against 14 per cent with a subsuperior proper.

Primarily the subsuperior zone lies in the posterior sector of the lobe, but it may spread laterally or medially. It is a common site of lung abscess.

The basal bronchi are four in number and tend to radiate from above downward into the anteromedial, anterolateral, posterolateral, and posteromedial sectors of the lobe, respectively.

The medial-basal segmental bronchus (B^7) is the highest in origin. It extends to the zone that lies on either side of the pulmonary ligament (78 per cent of specimens), and is placed athwart the other basal zones—that is, it occupies a plane virtually at right angles to the others. This segment corresponds to the cardiac lobe of mammals. Therefore, it is not surprising to find an incisure of varying depth separating it from the anterior-basal segment in 36 per cent of specimens. In two-thirds of this number the incisure is possibly deep enough to have been visible in a roentgenogram.

The bronchus to this "cardiac" region commonly divides into an anterior (B^7a) and a medial ramus (B^7b). The line between the two usually falls in the sulcus of the inferior vena cava.

In 14 per cent of specimens the medial basal bronchus is absent as such, the zone being supplied by one or two accessory rami from the adjacent bronchi— B^8 , B^* , or B^{10} .

Contrary to Brock, the zone prevailing occupies two-thirds or more of the anterior margin of the lobe, and contrary to Jackson and Huber it usually extends onto the paravertebral surface.

Because of the high accessible origin of its bronchus, the frequent presence of incisures, and the superficial position of this segment, it is deemed suitable for resection.

The anterior basal segmental bronchus (B^8) is remarkably constant. It arises from the anterolateral aspect of the basal trunk, a little below B^7 . It soon divides into a lateral (B^8a) and a basal ramus (B^8b). The former supplies the area on either side of the interlobar margin below the level of the interfissural crest. The latter supplies the lower part of this sector including the corresponding diaphragmatic area. Usually (50 per cent), B^8b occupies only the lateral one-third of the lower interlobar surface as measured along the inferior margin of the lobe, but in 16 per cent of specimens it extends as far medially as the sulcus of the inferior vena cava. In another 8 per cent it takes over the territory of B^7b . Occasionally the lateral ramus (B^8a) invades the superior segment.

Because of the high origin of B^8 , its fairly constant distribution, and the fact that its medial border is frequently marked by an incisure (36 per cent), it is also deemed suitable for resection.

SURGERY OF THE THORAX

The lateral basal segmental bronchus (B^9) arises deep within the lobe and is not considered to be readily resectable. It is absent in 8 per cent of specimens. Typically it divides almost immediately after its origin into a lateral (B^{9a}) and a basal bronchus (B^{9b}). The former ramus, when present (86 per cent), supplies the posterior lateral zone adjacent to the subsuperior. When absent, its territory is to the subsuperior. The basal ramus (B^{9b}) supplies the lower posterior lateral sector and the corresponding diaphragmatic area. When absent (8 per cent), its territory is taken over by B^{10} .

The posterior basal segmental bronchus (B^{10}) appears to be a continuation of the lower lobe bronchus—particularly the ramus B^{10b} which extends into the inferior, posteromedial corner of the lobe. Typically, B^{10} breaks up into three major branches. The highest is that which has been already described as the accessory subsuperior, $BX^*(10)$. It occurs in 86 per cent of specimens and is reflected upward or backward to supply the subsuperior segment. The two remaining major branches (the mediobasal, B^{10b} , and the laterobasal ramus B^{10a}) pass respectively to the paravertebral and posterior surfaces, and to the corresponding diaphragmatic sectors. Because of the inaccessibility of its origin, this bronchus, like B^9 , is not readily resectable.

An Analysis of Variations of the Segmental Bronchi of the Left Lower Lobe of 50 Dissected, and 10 Injected Lungs. ROGER M. BERG, EDWARD A. BOYDEN, and FRANKLIN R. SMITH. *J Thorac Surg*, 1949, 18: 216

A survey of the literature regarding the bronchopulmonary segments leaves one with the impression that the left lower lobe of the lung is a somewhat condensed or even defective version of the right lower lobe, that if one understands the pattern of the right side it is necessary to remember only one or two modifications—such as the union of medial and anterior basal bronchi—to comprehend the left.

Such at first was the experience of the authors. Soon, however, it began to appear that the left lobe, although capable of being compared with the right, is distinctive throughout. For instance, the ramus of the left superior segment have a different system of branching, the left subsuperior zone is prevalently posterolateral and not posterior, the left anterior basal and not the left medial basal is the "defective" bronchus, the lateral branch of the left lateral basal contributes to the subsuperior zone, and the left posterior basal, in a third of the specimens, was characterized by a prominent paravertebral ramus.

Hitherto, only Brock (1942 to 1944) seems to have made any detailed study of the variations of the lower lobe segments and he has largely confined himself to describing the varying extent of the segmental bronchi. The authors' purpose has been to establish the prevailing pattern in a large number of specimens and from this firm and hitherto unestablished base to analyze the significant and puzzling variations which are so frequently encountered.

In general, the terminology of Jackson and Huber (1943) has been employed, supplemented by the system of enumeration of bronchi developed by Boyden (1945). Also, throughout the article, the segmental pattern of the left lower lobe has been compared with that of the right, as was done by Smith and Boyden (1949).

An analysis of the bronchial tree of 60 left lower lobes is presented. The prevailing pattern and its variations are described and compared with those of the right lower lobe.

The superior segmental bronchus (B^8) has the same apparent mode of branching as on the right side, namely, a bifurcation, but it differs in formula—" B^{8a} and $B^{8b}+c$ " instead of " $B^{8a}+b$ and B^{8c} ". The lower and independent origin of B^{8a} in the left lung seems to permit a greater paravertebral extent in that it reaches the lower third of the paravertebral surface in 57 per cent of the specimens. As a consequence, the superior segment caps the basal segments obliquely, whereas on the right side its orientation is prevalently horizontal. This presents an anatomic hazard to the resection of this segment. A large posterior branch of this ramus, B^{8a2} , invades the posterior sector of the subsuperior zone in 45 per cent of the specimens.

The subsuperior zone is present in 100 per cent of the specimens. It is a wedge-shaped district that is interpolated between the superior and basal segments on the costal surface of the lobe. It derives its name from an independent dorsal ramus (the d_2 of Aebys) which arises from the stem bronchus below the superior segmental bronchus. This "subsupsuperior proper" (B^7) occurs less frequently on the left (29 per cent) than on the right side (62 per cent). In the left lung it extends primarily to the postolateral sector of the costal surface but it may spread laterally or posteriorly. (On the right side it extends primarily to the posterior sector.) When it is absent on the left, its place is taken by high posterior or posterolateral branches of the corresponding basal bronchi. These "accessory subsupsuperiors" may also supplement B^7 when it is present. (On the right side the zone is supplied primarily by B^7 and $BX^*(10)$. On both sides, according to Neil and others, the subsuperior zone is an important "site of localized pathologic change.")

The basal bronchi have generally been considered to be three in number—the anteromedial basal (B^7+), the lateral basal (B^9), and the posterior basal (B^{10})—and to arise as a trifurcation of the lower lobe bronchus. As a result of the detailed analysis of 60 specimens it is believed that both ideas should be revised. First, the prevailing mode of branching (87 per cent) is a bifurcation, the common formula (67 per cent) being B^7+ and B^{10} . Second, it would seem necessary to give B^7 and B^9 an independent status. Whether they should be called subsegmental or segmental bronchi is of lesser consequence.

The medial basal bronchus (B^8) arises with B^9 from a short common stem in 87 per cent of specimens. Consequently, in contrast to its homologue

SURGERY OF THE THORAX

life after an attack of atypical pneumonia. Conservative treatment is palliative but never curative in the established case. Recent advances in thoracic surgery have resulted in the development of a technique of partial or total pulmonary resection which makes possible eradication of the disease in many cases. An analysis of 96 cases in which 105 pulmonary resections were performed from January, 1933, to May, 1948, indicates that this treatment is not hazardous and gives satisfactory results in a high proportion of selected cases.

The essential diagnostic method is bronchography, by means of fluoroscopy and roentgenography following the instillation of a roentgenopaque substance (lipiodol) into the bronchial tree. It is essential that the entire bronchial tree be satisfactorily filled. The full extent of the pathologic process must be outlined and all normal lung sharply delineated. Only with this information can one proceed confidently with radical surgical procedures.

The type of treatment employed is based on the severity of the symptoms, the degree and extent of ectasia, and the age and physical condition of the patient. Minimal symptoms, however, do not warrant a radical attack. In the presence of significant symptoms surgical therapy must be considered. Pulmonary resection is the only form of surgical therapy which has proved satisfactory. The more localized the disease, the more amenable it is to resection. The more diffuse the pulmonary involvement, the more difficult the surgical problem, but careful segmental and lobar resections can eradicate even bilateral disease involving several lobes. In bilateral bronchiectasis, if the major involvement is on one side, the degree of relief obtained following resection of this portion of the pulmonary bed may be sufficient to obviate the necessity of resection on the second side. If extensive bilateral resections are contemplated, it is imperative that the residual lung be free of bronchiectasis.

Pulmonary resection is admittedly a formidable surgical procedure but the improvement in results over the years has been striking. Increasing experience in the evaluation and management of the patient, technical surgical refinements, effective antibiotics, and the increasing use of whole blood have contributed materially to the improvement in results.

The virtual disappearance of postoperative pneumonia, the chief cause of death, was coincident with the introduction of effective antibacterial agents and the institution of routine hilar dissection. The reduction in the incidence of empyema and fistula has been remarkable, although not as abrupt. Further technical refinements and the more effective use of antibiotics have contributed to this improvement. It has become increasingly apparent, however, that in the cases of partial pulmonary resection prompt re-expansion of the remaining pulmonary tissue to fill the hemithorax is of the utmost importance in the prevention of these complications. In order to accomplish this the bronchial tree must be constantly cleared of secretions. At operation two intercostal

tubes are placed, one anterior to the apex and the other posterior and low in the paravertebral gutter. These tubes are connected to a negative suction apparatus and remain for a few days until the lobe is well expanded and the pleural drainage minimal. Complete re-expansion usually occurs within from 24 to 72 hours. Postoperative pain has been reduced by the injection, at the time of operation, of all the intercostal nerves with a long-acting local anesthetic agent. This facilitates the encouragement of voluntary coughing which is the most important postoperative maneuver. The patient must be closely observed, examined, and assisted in coughing at frequent intervals the first few days. Nothing can replace this constant attention. Whenever spontaneous bronchial clearing is inadequate, intratracheal catheter suction should be used. The liberal use of whole blood preoperatively to correct anemia and to restore diminished blood volume in the debilitated, as well as prompt operative and postoperative shock, placement of all blood lost has prevented hastened convalescence, and, the authors believe, aided materially in aborting infection.

The progressive improvement in results with the reduction in morbidity and the practical elimination of fatalities as a result of the procedure make pulmonary resection an attractive therapeutic method. In this series there has been no hospital fatality in the last 92 operations. Subsequent death from pulmonary disease has occurred in 3.1 per cent of the cases. The incidence of irremedial unsatisfactory results has been 4.2 per cent. With present experience and facilities most of these unsatisfactory results should be completely prevented in the future. It therefore seems fair to state that pulmonary resection is indicated in any established case of bronchiectasis provided the disease is neither too mild nor too extensive, the patient is not elderly, and medical conditions are not contraindications.

JOHN E. KIRKPATRICK, M.D.

Primary Bronchiogenic Carcinoma: Correlation of the Recent Literature with 131 Proved Cases

JOHN J. O'KEEFE. *Arch. Int. M.*, 1948, 82: 345

O'Keefe analyzed 131 cases of proved primary bronchiogenic carcinoma and correlated the data as found in the recent literature.

It was seen that the incidence of this disease is absolutely, as well as relatively, increasing. Characteristically, it is predominantly a disease of white men between the ages of 45 and 60, it has a definite predilection for the right lung, and the average length of life of patients not amenable to surgical treatment is from 12 to 18 months.

Notable among the efforts to secure earlier diagnosis is the development of the technique of cytologic study of bronchoscopically removed secretions, this practice promises to increase the recognition of early cancer of the lung by an appreciable margin.

The management of patients with this neoplasm entails the evaluation of several factors: the location and degree of extension of the primary growth, the

SURGERY OF THE THORAX

An analysis of the delays incurred between the onset of symptoms and therapy are as follows

	1932-1942	1947-1948
	133 patients	
Patient's delay in seeing doctor	3 months	3 8 months
Interval between first symptom and establishment of diagnosis	11 75 months	10 months
First x ray examination ordered	3 months after seeing doctor	1 6 months after seeing doctor
Diagnosis established	5 75 months later	4 6 months later

The interval between the onset of symptoms and the diagnosis must be shortened, it can be altogether eliminated. The neoplasm can be discovered before it is large enough to produce symptoms since early carcinomas usually produce x-ray changes discoverable by the experienced observer even if the tumor itself will not cast a shadow, for approximately 80 per cent of the lesions are situated in a lobar or segmental bronchus. Roentgenologic screening of the population is necessary. Older age groups should be included and the screening should be repeated annually.

Surgical exploration is advised in all suspected or proved cases with but 2 exceptions

1 When there is absolute or strong presumptive evidence that the growth is out of bounds

2 When the patient's general condition is too precarious for a reasonable chance of success

In the same period (1932-1948) 27 bronchial adenomas were discovered. Among this group of patients there was no operative mortality, but 1 patient has died of metastasis. Of 26 patients subjected to follow-up study, 25 have lived from 5 to 15 years.

FRANK B. QUEEN, M.D.

Segmental Pulmonary Resection

DOUGLAS ROBB
Austral N Zealand J Surg, 1949, 18 217

This article deals with the practical aspect of division of lung tissue into units smaller than the five major lobes.

The lingula is frequently involved along, or in conjunction, with other sections in prognosis. The author points out that an avascular plane of cleavage can be dissected easily after ligation of the vessels to the area involved.

Another segment frequently attacked surgically is the apical, or first dorsal, segment of the lower lobe. This portion of the lobe is dissected in a similar manner. The same is true of the middle lobe of the right lung.

The author has also followed this procedure in the performance of lobectomies in cases with partial absence of fissures. The author has used this method of securing the bronchus and vessels and peeling the segments off through an avascular plane in 6 cases of segmental resection and in 1 case of lobectomy with poor or absent fissures.

He points out that it is necessary to have good preliminary bronchograms in at least two projections

so that, as nearly as possible, the plane of action may be mapped out before operation. His post-operative bronchograms in 3 cases have shown excellent immediate results except for some unavoidable distortion. There was no bronchiectasis, and the remaining segments seem to have good aeration.

ROBERT E. FLORES, M.D.

The Occurrence of Infection after Pulmonary Resection

CARROLL C. MILLER and RICHARD H. SWEET
N England J M, 1949, 240 589

Four hundred and twenty-seven cases of lung resection at the Massachusetts General Hospital, Boston, between 1942 and 1947 have been reviewed with the specific intent of correlating the trend of post-operative morbidity and mortality rates with the use of chemotherapeutic and antibiotic medications. During this 6-year period, sulfonamides, penicillin, and streptomycin were used singly and in combination with one another. In addition to these agents, the following advances in surgical technique contributed strongly to the improvement in postoperative results: the diminishing use of tourniquet lung resection and adoption of individual ligation methods in dealing with hilar structures, the careful suture of the bronchus with a single row of interrupted fine silk sutures, and complete capping of the closed stump with a pleural flap.

The cases have been divided into four major categories: bronchiectasis, lung abscess, tuberculosis, and carcinoma. The incidence of empyema, the duration of hospitalization, and the operative mortality due to septic and nonseptic causes have been considered for each disease for each year. A significant decline in each of these factors was noted during the period from 1942 to 1947, it was accompanied by the increasing use of particular types of drug agents. Often it was observed that patients showed little or no preoperative response, as shown by their temperature charts, to chemotherapeutic agents, but their postoperative course appeared much smoother than would have been expected without such medication.

The preoperative use of aerosol is advised in patients with bronchiectasis. The injection of penicillin and streptomycin into the pleural cavity in cases of frank empyema is advocated. The efficacy of sulfonamides and the value of penicillin and streptomycin are evident from the results.

The present routine for these chemotherapeutic agents consists of the intramuscular injection of 300,000 units of penicillin (100,000 units every 8 hours) and of 1 gm of streptomycin (0.25 gm every 6 hours) daily for 2 days before operation. When fever or other signs of infection are present, as indicated by profuse sputum or roentgenological examination, penicillin is administered from 7 to 10 days preoperatively. Aerosol penicillin, 50,000 units in 1 cc of normal saline, with or without streptomycin is given four times a day when expectoration is abundant. At operation before the chest is closed, 100,000 units of penicillin and 1.0 gm of streptomycin dis-

solved in 30 cc of normal saline are instilled into the pleural cavity. The value of this cannot be evaluated at present, but its use appears justified. The intramuscular injection of both drugs (100,000 units of penicillin and 0.25 gm of streptomycin every 6 hours) is continued postoperatively for 5 or 6 days, or until the patient's temperature chart has been normal for 3 days. At present streptomycin and penicillin are administered in all cases of lung resection.

Early postoperative bronchoscopic aspiration should be used when there is failure of lung expansion as a result of bronchial obstruction and prompt thoracentesis should be done in the presence of appreciable effusion. It is believed that penicillin and streptomycin minimize the tendency for the development of pneumonitis in postoperative atelectatic areas.

C. FREDERICK KITTLE, M.D.

HEART AND PERICARDIUM

Aspiration of Blood from the Pericardium in the Treatment of Acute Cardiac Tamponade after Injury. Further Experience, with a Report of Cases. MARK M. RAVITCH and ALFRED BLALOCK. *Arch Surg*, 1949, 58: 463.

Five years ago the authors reported their experience with the aspiration of blood from the pericardial cavity in the treatment of acute cardiac tamponade due to hemopericardium. At the time of this report, the results led to the conclusion that aspiration of the pericardial contents is the treatment of choice for hemopericardium and that open operation should be resorted to only if bleeding continues or is resumed. Blau, Anderson and Starbuck, and others have reported successful results with non-operative treatment. Since this previous report, there has been an improvement in the mortality rate associated with the operative treatment of wounds of the heart.

Since this report, there have been admitted to the Johns Hopkins Hospital, Baltimore, Maryland, a total of 8 patients with cardiac tamponade due to wounds of the heart. Seven of these patients were treated by pericardial aspiration and the usual supportive measures. All survived without complications. The eighth patient, shot through the heart, failed to respond to aspiration of 7 c.c. of the pericardial blood and was thought not to have a tamponade. Exploration revealed a through-and-through wound of the heart, with penetration of the right pulmonary hilus. The patient died of ventricular fibrillation. A patient with a stab wound of the neck bleeding into the left thoracic cavity was subjected to immediate thoracotomy. A wound of the left auricle was successfully sutured. The cases are recorded in detail later in this article, and the available data in 4 instances are presented in graphic charts. No other patients with heart wounds were admitted to the hospital during this period. The cases of patients who died in the accident room and therefore were not admitted to the hospital are discussed separately.

The authors continue to be impressed by the simplicity, and regularly successful outcome, of pericardial aspiration. Aspiration is performed in the left fourth or fifth interspace parasternally with a 16 or 18 gauge needle. The quantity of blood in the 7 cases reported varied widely, from 12 to 305 c.c. (the latter amount being obtained in two aspirations, 4 minutes apart). In all these cases there was an unequivocal cardiac tamponade. In some of them, as in Case 4 in which the venous pressure did not reach a normal level for several days, it can safely be assumed that aspiration removed only a portion of the blood from the pericardial cavity. A salient feature of the treatment is the striking rapidity of clinical improvement after removal of blood from the pericardium.

The usual clinical picture is that generally described. The standard signs of tamponade are low arterial pressure, elevated venous pressure, distant or absent heart sounds, decreased or absent cardiac pulsations as seen with the fluoroscope, and the usual concomitant signs of shock. In addition, there is the frequent occurrence of a relatively slow heart beat, when any is detectable, and the common occurrence of wild excitement in patients not completely prostrated. The electrocardiogram, even when taken in the first few minutes of treatment, has shown no specific change, except in Case 11, in which the diagnosis of an injury of the coronary artery was made during life and demonstrated at autopsy. In several of the patients some degree of hemothorax subsequently developed, which conceivably would indicate a leakage of pericardial fluid into the chest, and prevent the delayed development of tamponade. It is particularly interesting that of the 8 cases, including Case 11, in which tamponade was successfully treated by aspiration alone, 3 were of bullet wounds, 3 of knife wounds, and only 2 were of ice pick wounds. Therefore, the type of the weapon used to inflict the wound need not affect the treatment.

The possibility of cardiac tamponade is kept in mind in any case of thoracic wound, particularly if it is precordial, and all such patients are closely watched. In Case 1, signs of tamponade developed under observation during a period of almost 2 hours. Fluoroscopic examination and pericardial aspiration are the most helpful diagnostic measures. Arterial pressure and venous pressure should respond steadily after aspiration, and these, with the heart sounds and fluoroscopic findings, form the basis for evaluation of improvement. If improvement ceases or is not maintained at a satisfactory level, aspiration is repeated, as in Case 8, in which 305 c.c. of blood were aspirated in two attempts, 165 c.c. and 140 c.c., respectively. If a second aspiration should fail to give relief, the plan is to take the patient to the operating room for cardiorrhaphy. The operating room is always alerted as soon as a patient with a wound of the heart is received in the accident department. It is the authors' practice to take patients suspected of pericardial tamponade directly to the fluoroscopic room in the accident department and to perform all examina-

SURGERY OF THE THORAX

tions and treatment of the patient on the fluoroscopic table, with frequent observation of the heart. A needle is at once placed in a peripheral vein, and the administration of plasma is started prior to the giving of whole blood. At times, dextrose injection in isotonic sodium chloride solution (U S P) is injected preliminary to the administration of plasma. The administration of whole blood is continued until the patient's condition and blood pressure are stabilized at a satisfactory level. It would appear that in most cases of wounds of the heart which are not immediately fatal, bleeding is controlled and arrested by the tamponade and does not recur when the tamponade, which is now the life-threatening condition, is relieved by aspiration. Thus far we have seen no recurrence of symptoms of tamponade once the initial symptoms have been relieved.

Seven consecutive patients with pericardial tamponade due to hemopericardium were successfully treated by aspiration alone, 1 patient was successfully treated by immediate cardiorrhaphy, and 1 patient without tamponade died as a result of a perforating bullet wound of the heart and pulmonary chest from a laceration of the left auricle was successfully treated by suture of the auricle. One patient with cardiac tamponade due to a bullet wound responded well to aspiration, only to die abruptly 2 hours after he was first seen. Autopsy showed vision of the anterior descending branch of the left coronary artery, fresh infarction of the left ventricle, and evidence of cardiac failure with pulmonary edema. Three additional patients died of heart wounds within 5 minutes of being admitted to the accident room. A fourth lived 55 minutes and might have been saved, but was thought not to have a penetrating wound.

Pericardial aspiration is the most important initial treatment for cardiac tamponade due to wounds of the heart. Facilities for open operation should be held in readiness, but it appears that with most wounds which cause cardiac tamponade and are not immediately fatal aspiration alone will suffice. The administration of blood and plasma is an important adjuvant.

JOHN E. KIRKPATRICK, M D

ESOPHAGUS AND MEDIASTINUM

Some Rare Anomalies of the Esophagus A S HANDOUSA BEY *J Lar Olol*, Lond, 1949, 63 217

The author discusses some rare anomalies of the esophagus and speculates on their cause. Four cases are reported, the first 2 being those of diverticulosis of the upper end of the esophagus, and of the thoracic portion. The diverticulum of the upper area was found opposite the second and third thoracic vertebrae, and on radiologic examination there appeared to be pouches, forming a pear-shaped shadow. The upper and larger one communicated directly with the pharynx by a wide opening, whereas the smaller one was connected with the left side of the main diverticulum.

The patient was a 20 year old girl whose diverticulosis was symptomless until she swallowed a medallion which obstructed her food passage. On removing the medallion complete relief was obtained, and for this reason surgery was considered inadvisable.

The second case was that of a fully developed true diverticulum of the middle third of the esophagus in a woman 40 years of age. This was considered a traction diverticulum, the cause of which is an acquired pressure from the inside forcing the mucosa through a vascular foramen, although a congenital origin cannot be excluded in this patient.

The third case was that of congenital stenosis caused both by a stricture and a membranous diaphragm present in one position.

The fourth case was one of a hypertrophied, enormously elongated esophagus with two large coils in a 24 year old male patient. The coils moved about and appeared to have a mesentery. The anomaly is comparable to the condition known as dolichocolon and to megacolon of the large intestine.

Congenital malformation is considered an important function in the formation of these abnormalities.

From a study of these 4 cases, it may be concluded that diverticula of the esophagus are not so rare as supposed. Many are not discovered because they are symptomless, others are found incidental to systematic radiologic study, and because of this fact it is believed that surgery is not necessary in every case and that the patient may live contented with his congenital anomaly without any serious compromise to his health.

STEPHEN A. ZIEMAN, M D

Statistical Contribution to the Subject of Surgery of the Mediastinum (Contributo casistico alla chirurgia del mediastino) ANGELO PALETTO *Ann Ital chir*, 1948, 25 609

A clinical discussion of 15 cases of tumor of the mediastinum is presented. The term 'tumor' is used broadly to designate any intramediastinal space-restricting process acting more or less like a tumor. This material included 2 cystic tumors (an echinococcus cyst and a histologically unspecified blood cyst), 3 fibromas, 2 tumors of nervous origin (a neurofibroma and a ganglioneuroma), 3 carcinomas, 4 lymphogranulomas, and 1 inflammatory mass. The usually so prevalent dermoid cyst was absent in this group of patients and retrosternal goiters were not included. Of these 15 cases, 2 were chance findings and 4 did not present symptoms characteristic of mediastinal compression.

The surgical method used in 6 cases was that of approach through the posterior mediastinum, through a curvilinear paravertebral incision, with every precaution not to open the pleura. This method is indicated in the cases in which the mass is not larger than an orange and is located well back in the posterior mediastinum.

In 2 of the patients the method used was that of posterior mediastinotomy with a transpleural ap-

proach This method is indicated in tumors much larger than those mentioned, which have invaded the tissues of the mediastinum more extensively Of the remaining 4 cases which were adjudged operable, 1 was a substernal carcinoma for which anterior mediastinotomy was done and 3 were lymphogranulomas for 2 of which decompressive median sternotomy was done, anterior mediastinotomy was done for the third In none of these was any attempt made to remove the tumor and death occurred soon after the operation in 3 The remaining case (lymphogranuloma) is still under irradiation treatment Of the remaining 3 patients, 2 were adjudged inoperable, and the other did not seem to need any operative procedure as he had a lymphogranuloma which was not causing any symptoms

Viewed causally, the figures on results do not appear encouraging There were 12 surgical interventions However, 5 of these were done as a last resort, with thought only of relief from the eminent asphyxiation, even so, in 3 patients such relief could not be attained In the other 2, a biopsy for diagnostic purposes was all that could be accomplished The operation on the hemorrhagic cyst was certainly a mistake, because of the error in diagnosis The remaining 6 patients seemed more amenable to curative surgery The masses were smaller and were favorably located in the posterior mediastinum In fact, in 4 of these 6 patients clinical cure was obtained, although the echinococcus cyst ruptured into the pleural cavity during removal The patient died later from recurrence at this point Of the re-

maining 2 patients, 1 died of postoperative circulatory collapse and 1 died later of septic sequelae

The report of these 15 cases, observed during the prepenicillin era, may seem an anachronism in view of some of the brilliant, recently published results However, the material will serve as a contrast for the better results which, with the advent of newer therapeutic agents and newer surgical techniques, may be anticipated for the future

JOHN W BRENNAN, M.D

MISCELLANEOUS

Surgical Problems of Retained Intrathoracic Foreign Bodies GEORGE N J SOMMER, JR., and CHARLES S MCCOLLOCH *Am J Surg*, 1949, 77 314

The operative treatment of 187 patients with foreign bodies lodged in the chest is reported Of these, 35 were in the parietes

Foreign bodies causing pain, hemoptysis, or ex pectoration, and asymptomatic foreign bodies 1 cm or more in two dimensions, should be removed Intrathoracic foreign bodies which are adjacent to the heart, the great vessels, or the esophagus afford definite indications for removal

Since pathogenic micro-organisms may be cultured from the sites of about 85 per cent of intrathoracic foreign bodies, even if they are asymptomatic, and since the removal of these foreign bodies is attended by low morbidity and mortality rates, elective removal of them is advised SAMUEL KAHN, M.D

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

The So-Called Hernia of the Semilunar Line of Spigelius (Sulle cosiddette ernie della linea semilunare di Spigelio) NATALE DI MOLFETTA *Arch ital chir*, 1949, 71 103

The author encountered a patient with a hernia along the semilunar line of Spigelius which stimulated him to study the anatomy of this region, however, the patient refused operation

The author was not satisfied with the explanations offered in the texts, especially as to the anatomy of this region, and performed numerous dissections on cadavers of all ages with no satisfaction. He then resorted to microscopic study of fetuses varying in length from 7 to 30 cm and also made sections on a 2 year old, a 15 year old, and an adult

Following careful study of these sections he concluded that the aponeurosis of the large muscles of the abdomen, which at the lateral margin of the rectus muscle pass dorsally to form the posterior leaf of the rectus sheath, continue to pass in the subumbilical region. They do not pass toward the ventral surface as is usually stated in treatises on anatomy. They thin out and fade, leaving the dorsal surface of the rectus muscle in the suprapubic region unprotected

The same findings are present in the fetus, in which the definite compartment is lower than in the adult

Hernias found along the semilunar line of Spigelius probably arise in the thinned and frayed out portions of the posterior sheath and then point at the semilunar line. Hence, the so-called "hernia of the semilunar line of Spigelius" is a vague entity

On repair of hernias in the lateral margin of the rectus muscle careful study of the anatomy will reveal facts which will illustrate the pathogenesis of these hernias

LUCIAN J. FRONDUITI, M D

The Strangulation of Diaphragmatic Hernias (L'ètranglement des hernies diaphragmatiques) JACQUES MICHON *J chir*, Par., 1949, 65 25

A man of 24 years developed acute symptoms of obstructive ileus with pains in the left epigastrium irradiating to the inferior angle of the scapula and to the mammillary region. Roentgenography after a barium enema revealed complete arrest of the barium at the splenic flexure. The laparotomy confirmed the diagnosis of strangulated diaphragmatic hernia of the left extremity of the transverse colon

As it was not possible to disengage the hernia from the abdominal cavity, the paraumbilical incision was extended upward and outward, and a thoracophrenotomy was performed in the seventh interspace. The diaphragm was resected to free the strangulated gut and closed with suture. The patient recovered after a stormy postoperative period

The author discusses the pathogenesis, symptomatology, and treatment of diaphragmatic hernias in general. He emphasizes the importance of early surgery and the danger of pneumothorax with thoracophrenotomy

WERNER M. SOLMITZ, M D

Hiatus Hernia G G RICHARDS and K A CROCKETT *Arch Surg*, 1949, 58 411

The authors report on 24 cases of hiatus hernia observed in the last 18 months and note that this was a greater number than was found in the previous 30 years. The ages of the patients varied between 33 and 68 years, 3 patients being under 45 years of age. There were 17 men and 7 women, and 16 patients were overweight. All but 1 patient complained of either epigastric or substernal pain and 7 of these had radiation of pain into the left shoulder or arm. Only 1 had dysphagia. Two patients had gastrointestinal hemorrhages with anemia. The average duration of symptoms was from 6 months to 20 years. Practically all the patients had been treated for other conditions previously

It is pointed out that hiatus hernia must be kept in mind in any case of atypical angina pectoris, duodenal ulcer, dysphagia, disease of the gall bladder, anemia from gastrointestinal bleeding, obscure upper abdominal pain, or pain in the lower part of the chest which might be associated with increased intra-abdominal pressure. Special fluoroscopic technique is essential to determine the true incidence of this condition

JOHN L. LINDQUIST, M D

Differential Diagnosis of Hiatus Hernia and Coronary Artery Disease ARTHUR M. MASTER, SIMON DACK, JACOB STONE, and ARTHUR GRISHMAN *Arch Surg*, 1949, 58 428

The authors emphasize the increasing incidence of hiatus hernia and coronary artery disease and the fact that the two conditions may coexist, so that the presence of one condition does not exclude the other. By means of objective tests the presence of coronary disease can be ascertained and its relative importance properly evaluated

In a clinical investigation of this problem the two-step exercise and anoxemia tests were used on 57 patients with positive roentgenologic evidence of hiatus hernia. To ascertain the presence or absence of organic heart disease the following clinical determinations were made

A complete history was obtained, physical, tele-roentgenographic and roentgenoscopic examinations were made, the resting electrocardiogram, including augmented unipolar extremity and Wilson precordial leads, was obtained, and the two-step exercise electrocardiogram and the 10 per cent anoxemia test were made

On the basis of symptoms the patients were divided into 4 groups. Group 1 comprised 15 patients

with purely gastrointestinal symptoms, group 2 comprised 29 patients with gastrointestinal and cardiac complaints, group 3, 3 patients with only cardiac complaints, and group 4, 10 patients with symptoms attributable to anemia secondary to hemorrhage.

Evidence of organic heart disease was found in two-thirds of the cases. Four patients of group 1 had pain referred to the left side of the chest, but no evidence of coronary disease was obtainable. In 23 of the 29 patients in group 2, cardiac disease was demonstrated by the objective examinations. In the 6 remaining patients with thoracic pain suggestive of angina pectoris, organic coronary disease could not be demonstrated, which suggested that hiatus hernia may have been the only factor initiating pain.

These negative findings in the latter cases also indicate that the history alone is not a safe means of differentiating hiatus hernia from angina pectoris due to coronary artery disease. Nevertheless, the history may be helpful, for the occurrence of epigastric or substernal discomfort in the recumbent position which is relieved on standing is characteristic of hiatus hernia, whereas constant relation to effort and prompt relief by the use of nitroglycerine is more suggestive of coronary artery disease. Hiatus hernia not infrequently may precipitate coronary insufficiency even in the presence of normal coronary arteries if hemorrhage, severe anemia, or shock develops.

JOHN L. LINDQUIST, M.D.

The Mechanism of Shock in Peritonitis RICHARD V. EBERT, PAUL S. HAGEN, and CRAIG W. BORDEN
Surgery, 1949, 25: 399

During the recent world war the observation was made that severe and irreversible shock frequently occurred with penetrating abdominal wounds in which there was fecal contamination of the peritoneal cavity. Certain of the patients had a good initial response to supportive therapy and then developed a secondary fall in arterial pressure which did not respond to further transfusions even though blood volume was elevated and maintained at normal.

This study to elucidate the hemodynamics of the shock occurring in patients with fecal peritoneal soiling was carried out on 15 dogs. The peritoneum was soiled by pouring liquid feces into the abdominal cavity. The dogs were divided into three groups: the untreated, the inadequately treated, and the treated. The treated dogs received enough plasma to maintain the arterial pressure until the terminal fall and the blood plasma volume was as close to normal as possible. The untreated and inadequately treated dogs developed severe shock in from 3 to 10 hours. The shock was characterized by a decrease in arterial pressure, hemoconcentration, low plasma volume, and a fall in the cardiac output. There was an increase in peripheral resistance in 5 dogs and a decrease in 2 dogs. The shock, therefore, resembled the shock caused by hemorrhage.

In the group of 5 animals adequately treated, as defined by a relatively normal blood volume, a marked fall in arterial pressure occurred in from 6 to

11 hours. The plasma volume was normal or only slightly decreased and there was no evidence of hemoconcentration. Although the mean arterial pressure was markedly reduced, the cardiac output remained unchanged or was slightly elevated above control level. Therefore, the total peripheral resistance was reduced in all cases, the average value for the group being 5,490 during the control period and 2,300 during the period of shock. Cultures of the blood consistently yielded bacilli of the colon group. Transfusions did not prolong life.

The authors call attention to the difference between the shock in the adequately treated dogs with peritonitis and the irreversible shock which may follow severe hemorrhage. Hypotension was avoided in the treated dogs, and the cardiac output remained normal by replacement of the plasma lost into the peritoneal cavity. Nevertheless, vasodilatation and consequent decrease in peripheral resistance occurred. The latter phenomena are not explained by this study.

FREDERICK C. HOEBEL, M.D.

The Surgical Anatomy of the Inferior Mesenteric Artery and Sudeck's Point (*L'anatomia chirurgica dell'arteria mesenterica inferiore ed il punto del Sudeck*) GAETANO BALICE
Gior ital chir, 1949, 5: 1

The author studied the circulation of the inferior mesenteric artery in 30 cadavers by injecting methylene blue into the artery. A detailed drawing was made of the artery in each of the cadavers, and all drawings are reproduced in the present article. The so-called normal pattern of the inferior mesenteric artery was found in only 7 (23%) cases, however, Sudeck's point was found in 25 (90%) of the cases. The author stresses the fact that great variations occur, and he believes that even though Sudeck's point is found in a high percentage of cases, it does not exempt the surgeon from exposing it plainly in cases in which a high rectosigmoid resection is performed.

LUCIAN J. FRONDUTI, M.D.

GASTROINTESTINAL TRACT

Massive Hematemesis CYRIL COSTELLO
Ann Surg, 1949, 129: 289

In seeking to learn the best methods of management of massive hematemesis, from the rather vast literature on the subject, one encounters a divergence of opinion as to whether treatment should be medical or surgical, and, if the latter, how the cases are to be selected. Other problems in therapy concern the question of the advisability of using gastric siphonage, oral feeding, blood transfusion, and sedation. Three hundred patients who presented the symptoms of massive and severe hematemesis were selected for the present study. No patient was included in the study who had not vomited large quantities of gross blood and who did not show evidence of blood loss by shock or severe anemia, or both.

The causes of hemorrhage in the patients studied were as follows: (1) chronic duodenal ulcer was the

underlying cause in 171 patients, (2) acute gastritis was believed to be the cause in 42 cases, (3) chronic gastric ulcer was seen in 33 patients, (4) ruptured esophageal varices occurred in 24 patients, (5) chronic gastritis occurred in 12 patients, (6) gastric carcinoma accounted for 4 cases, (7) marginal ulcer for 4, (8) curling ulcer for 2, (9) carcinoma of the esophagus for 3, (10) gunshot wound in 1 patient, and (11) no determinable cause in 4 patients.

The incidence of massive hematemesis was greater between the fourth and eighth decades, nearly a fourth of cases occurring in the sixth decade, 82 per cent of the patients were males and 18 per cent were females.

The overall mortality rate in the 300 cases was 25 per cent. Consistent with other reports on the same subject, it was seen that the mortality rate increased in those patients who had reached or had passed the fifth decade of life. Examination at operation or at autopsy permitted the pathological study of about 85 per cent of those patients who died. The eroded blood vessels in particular were examined, and in nearly all microscopic sections there was seen a partial or complete block of the eroded vessel wall by antemortem thrombus. The author believes that this demonstration of thrombus formation even in large eroded arteries is of paramount importance in arriving at a rational plan of therapy. It was evident that many of these patients did not die, as has been commonly assumed, from acute exsanguination through a wide open artery, but rather because of the complications of diminished blood volume such as shock, cardiac failure, anemia, and pneumonia. This fact was confirmed from the clinical course of patients who died, for death occurred not in a matter of minutes or hours (with one exception) as would be expected from a persistent fulminant hemorrhage, but the fatal outcome ensued after from 2 days to 3 weeks following the onset of bleeding. Hence, the author argues it is a misconception that patients suffering from arteriosclerosis or chronic ulcers should be subjected more promptly to operative closure of the bleeding point. Rather, he believes, therapy should be directed toward support of the depleted blood volume.

The body response to massive blood loss is well known to conserve the remaining blood for vital centers there is a generalized vasoconstriction, an increased heart rate, and absorption of tissue fluids into the general circulation. If inadequate blood volume continues, anoxia with irreversible tissue damage ensues. In view of this universally accepted fact, it is surprising to find recommendations that blood should be used sparingly or not at all. The theory that restoring blood pressures tends to "blow out" a forming thrombus has no scientific substantiation, to wait for a fall of blood pressure to 80 or 100 mm of mercury before administering a "small transfusion," as is often recommended, is a direct contradiction of sound physiologic principles.

If these pathologic facts and physiologic principles are correct the ideal treatment of massive hemate-

mesis should be prompt replacement of as much blood as has been lost until thrombus formation has sealed off the eroded vessels. To test these principles a further 73 patients were selected, corresponding closely in age and sex to the 300 patients previously considered. Operative interference during active bleeding was not undertaken in any of the 73 patients, treatment consisting of adequate and prompt blood replacement. Feedings were usually administered, and the type of feeding varied between the Meulengracht diet, the Sippy diet, a liquid diet, and protein dextrimaltose (pre-digested) liquids. The difference in mortality rate was striking. Only 4 per cent of this group of 73 patients died, as compared to 25 per cent of the 300 patients treated by various methods.

The total quantity of blood required for replacement is often enormous as compared with transfusion standards of a decade ago. As much as 3 or 4 liters were frequently administered during the first 24 hours in the hospital. The author condemns the frequent use of saline solution as this does nothing toward re-establishing blood volume, and encourages pulmonary edema. Plasma is the most valuable fluid for use while blood is being crossmatched. The need for blood cannot be determined by a patient's general appearance, pulse, or blood pressure, and the older methods of blood study, such as the blood count and hematocrit, are either undependable or too time-consuming. The copper sulfate falling drop method for determining specific gravities of whole blood and plasma, frequently repeated, gives the best indication of blood replacement needs. The test is simple, rapid, and readily performed by the initiated house officer.

Adequate continuous sedation is indicated, and this is best accomplished by an initial dose of morphine followed by hypodermic injection of 2 gr of sodium phenobarbital every 2 hours as needed to keep the patient drowsy.

The following procedure during the actively bleeding stage were found to increase the mortality: (1) surgery, (2) indwelling stomach tube with constant suction, (3) gastric lavage, and (4) active gastric diagnostic studies.

Following the control of hemorrhage and the restoration of nutrient and blood essentials, the advisability of elective surgical intervention may be more easily determined. WAYNE FIELD CAMERON, M.D.

Neurinoma in the Gastrointestinal Tract JOHAN CEDERMARK *Acta chir scand*, 1949, 97: 473

An account is given of the incidence, pathology, and clinical symptoms of neurinomas in the stomach and in the small intestine, based on a material comprising 2 cases of gastric neurinoma and 4 cases of neurinoma of the small intestine observed by the author, and 14 cases of gastric neurinoma and 6 cases of neurinoma of the small intestine from other Swedish hospitals.

Pathologically, the tumors are described as having derived from Auerbach's plexus or the submu-

cous plexus In the clinical account, the author emphasizes the long duration of the disease and the occurrence of hemorrhages, especially melena, which may give rise to a considerable anemia

Roentgen examination may be an aid in the diagnosis of a gastric neurinoma, but in none of the cases of neurinomas in the small intestine has x ray examination been of any help The tumors may be accompanied by fatal complications such as severe anemia, peritonitis, and malignant development The treatment is surgical and, when instituted early, may give a good prognosis

JOHN J MALONEY, M D

A Contribution to the Recognition of Severe Complications of Gastrointestinal Neurofibromatosis (Contributo alla conoscenza delle complicazioni gravi della neurofibromatosi gastrointestinale)
VINCENTO TRUGLIO *Sicilia med*, 1949, 6 57

The author describes a case of neurofibromatosis involving the skin and gastrointestinal tract The skin nodes first appeared about 20 years before the patient was seen by the author Ten years later a gastroenterostomy was performed for symptoms of gastric ulcer The patient felt well until the last year when she began to have recurrence of nausea, vomiting, and hematemesis Her condition became progressively worse and when she entered the hospital it was too critical to consider surgery She died of supervening bronchopneumonia

At autopsy she was found to have extensive neurofibromatosis involving the entire skin except the palms and soles of her hands and feet The stomach revealed a stenosing ulcer near the pylorus with a neurofibroma at its base Numerous nodes were present near the ulcer and over the site of the anastomosis The mucosa of the jejunum near the anastomosis showed numerous ulcerations which corresponded to subserous nodes

The author wishes to stress the severe complications other than malignancy (pyloric stenosis, hemorrhage, anemia, cachexia) which may complicate gastrointestinal neurofibromatosis

LUCIAN J FRONDOTI, M D

The Vascularization of the Human Stomach A E BARCLAY and F H BENTLEY *Brit J Radiol*, 1949, 22 62

The authors studied the vascularization of the human stomach by their remarkable technique of microarteriography which was so successfully applied to the kidneys a few years previously

Two kinds of opaque substance were used—one for the visualization of arteries and their branches down to the arterioles, the other for the finer vessels arising from the main plexus These were injected at a pressure of 150 mm of mercury into the arteries of the stomach excised at operation (for duodenal ulcer), or removed from the cadaver Arteriograms of the stomach wall were made first, then selected areas were sectioned transversely and subjected to the process of microarteriography

The opaque substance chosen for the demonstration of the arteries and their larger branches consisted of a 20 per cent solution of "chlorbismol," a proprietary preparation of bismuth oxychloride This was injected into one of the gastric or gastroepiploic arteries The chlorbismol has a particle size too large to enter the capillaries and produces perfect arteriograms It was noted in cadaver stomachs that the larger arteries form a plexus of very profuse anastomoses which are located in the submucosa and extend over the wall of the entire stomach These anastomoses are of large size so that on dissection they can readily be seen by the naked eye Their intercommunication is so extensive that injection of a single gastric or gastroepiploic artery is sufficient to fill the entire plexus of both anterior and posterior stomach walls, and even the other gastric and gastroepiploic arteries, by retrograde pressure

For visualization of the finer vessels, a suspension of 10 per cent colloidal silver iodide was used which has smaller particle size than the chlorbismol Very good microarteriograms were obtained It was found in cadaver stomachs that the finer vessels arise from the main plexus in the submucosa, and run through the muscularis mucosae towards the under aspect of the mucous membrane where they form a plexus of intricate anastomoses From this plexus arises a rich vascular network, the terminal vessels running perpendicularly through the mucosa towards the surface of the stomach wall

The injection of the stomachs removed at operation lead to an entirely different pattern In all specimens (12 altogether) it was difficult to find an area of mucous membrane in which the opaque medium had reached the peripheral circulation This suggested that the blood from the arteries of the submucosal plexus was shunted directly into the gastric veins

On the analogy of the work on the renal circulation it was thought that the shunt most probably is the result of operative trauma due to disturbance of the autonomous nervous system To prove this the change in oxygenation of the blood of the arteriovenous shunt was determined in 6 patients at operation After opening the peritoneum a sample of blood was taken as quickly as possible from a venous tributary running towards the lesser curvature, and a second sample was taken 3 minutes later from an adjacent vein The percentage of oxygen saturation of the first sample was 74 per cent, and of the second sample 91 per cent This rapid change in oxygenation proved that the blood passed directly from the arterial to the venous side

Additional experiments were performed to demonstrate the sympathetic nature of the shunt A patient for gastrectomy was anesthetized with a combination of general and high spinal anesthesia (reaching up to the level of the first to second thoracic vertebrae) The resulting microarteriograms showed complete filling of the mucosal vessels in a manner similar to that observed in cadaver stomachs In other words, blocking of the sympathetic outflow

T LEUCUTIA, M D

Gastric Ulcer CLAUDE E WELCH and ARTHUR W ALLEN
N England J M, 1949, 240 277

The authors review the management of patients with gastric ulcer, on the basis of cases studied at the Massachusetts General Hospital, Boston, during the 10 year period from 1938 to 1947 inclusive, with special reference to the ulcer-cancer relation, the treatment of the most common complication of gastric ulcer (hemorrhage), and the development of a satisfactory operative technique, especially for ulcers about the cardia

A total of 512 cases were studied. A large majority of patients were from 40 to 80 years of age, and the average age of patients was 55. The average duration of symptoms before admission was 5 years, placing the average age of onset of the disease at 50 years. This is considerably older than the average age of onset in duodenal ulcer, which is 30. The disease was three times as common in males as it was in females.

The percentage of error in the diagnosis of cancer in gastric ulcers is shown in Table I. This percentage has been reduced from 14 per cent in a previous study to 10.8 per cent in the present study, probably because of improved roentgenographic techniques and gastroscopy.

A short history of gastric ulcer in a patient 50 years of age or over was found to be highly suggestive of cancer. The radiologic diagnostic error was found to be highest in the region of the cardia, less in the prepyloric area, and least along the mid-lesser curvature. Malignant ulcers which were resected averaged 1.8 cm., while benign ulcers averaged 1.6 cm., so that size was not a definite criterion of malignancy. The presence of free hydrochloric acid is of no significance although its absence after the use of histamine is strongly suggestive of cancer. 90 per cent of histamine is found in approximately 90 per cent of patients with benign ulcers and of those with hydrochloric acid is found in approximately 90 per cent of patients with benign ulcers and of those with ulcer cancer. About 40 per cent of carcinomas of the stomach are accompanied by histamine achlorhydria.

A positive Papanicolaou smear of the gastric sediment indicates almost certain cancer, as only 4 per cent false positives are found. The presence of an accompanying active duodenal ulcer is strong evidence that the gastric ulcer is benign. Multiple gastric ulcers also suggest that the lesions are benign. Massive hemorrhage appeared in 6 per cent of cases of ulcer-cancer and in 9 per cent of benign ulcers. Pyloric obstruction occurred in 19 per cent of ulcer-cancers and in only 1.2 per cent of benign ulcers. Perforations, nearly always walled off by adjacent viscera, occur with about equal frequency in both groups.

The rate of healing was found to be the most reliable differential feature between benign ulcer and cancer. Although, on careful medical management, healing of a benign ulcer required a period of about 2 months, significant improvement was usually observed

after a period of 3 weeks, so that a decision could be made at the end of one month. Exceptions were observed in which cancers appeared to heal and then recurred, and a few benign ulcers failed to heal after months of treatment. From the results of their studies, the authors believe that operation should be performed in all but a small percentage of carefully managed cases.

Perforation of a chronic gastric ulcer along the lesser curvature is nearly always so gradual that the liver or pancreas walls off the lesion. Perforations of so-called acute gastric ulcers close to the pylorus are nearly always duodenal perforations. Pyloric obstruction, significant enough to be noted by x-ray examination, is much more likely to be due to duodenal ulcer or gastric cancer than it is to gastric ulcer. The demonstration of a gastric ulcer by roentgen study, combined with the clinical findings of partial or total pyloric obstruction, is therefore an absolute indication for operation. Hemorrhage is by far the most common and important complication, as it occurred in approximately 30 per cent of this series.

In cases in which the hemorrhage was severe, a difficult diagnostic problem was encountered, as ulcers were demonstrated roentgenographically in only half the cases. The overall death rate from hemorrhage was 9 per cent, the death rate was 4 per cent in patients treated surgically, and 12.5 per cent in those treated conservatively.

The authors believe there are three groups of gastric ulcers for which emergency operation is required. Patients in whom the condition can be diagnosed positively (by x-ray examination) as gastric ulcer and who have been bleeding less than 48 hours should be operated upon immediately. If bleeding has persisted for a longer time than 48 hours, but stops soon after hospital admission, the patient should be observed and treated medically until such time as normal blood and nutritional levels allow an elective gastric resection. Recurrence of hemorrhage indicates immediate operation in this group. A third small group is comprised of patients in whom the gastric hemorrhage fails to stop after the patient is admitted to the hospital and operation is indicated soon after his arrival. The same operative indications hold true in the absence of a positive x-ray diagnosis of ulcer provided pathologic lesions of the esophagus, especially varices and blood dyscrasias, can be excluded.

It appears that the particular ulcers that do poorly on medical treatment are the larger ones, particularly those over 2.5 cm. in diameter, those associated with obstruction, and recurrent ulcers with a long history

TABLE II — OPERATIVE MORTALITY

Operations	No of cases	No of deaths	Mortality Per cent
Partial distal gastrectomy	269	6	2.2
Partial proximal gastrectomy	14	3	21.0
Total gastrectomy	4	0	0
Miscellaneous	8	0	0
Totals	295	9	
Average			3.0

of gastric symptoms. Other factors did not illuminate the problem. It is suggested that a trial of medical therapy be reserved for patients in whom the ulcer is considered grossly benign by a competent roentgenologist and gastroscopist, and in whom symptoms have been present for less than 1 year—an ulcer that is 1 cm, or less, in diameter, located on the lesser curvature, and having a negative cytologic smear. If the x-ray diagnosis is equivocal, ulcerative lesions in a stomach with histamine achlorhydria, or those found elsewhere than on the lesser curvature or high in the cardia should also be treated immediately, by operation. Lesions of the cardia are permitted a period of medical therapy, despite the fact that the incidence of cancer is high, because the operative mortality for these lesions is still great enough to counterbalance the error in diagnosis of cancer. Failure of any of these ulcers to heal is an absolute indication for surgery.

Any operative procedure for gastric ulcer must change the gastric physiology so as to prevent recurrent ulceration and must be extensive enough to excise widely any carcinoma found. This limits the type of operation to some type of gastric resection.

A satisfactory resection consists of excision of at least 50 per cent of the stomach, encompassing the ulcer, and excision of both the greater and lesser omenta to include the regional lymph glands. The authors do not believe that vagotomy, gastroenterostomy, sleeve resection which does not include the omentum, or resection which does not include the ulcer, are adequate types of surgery. They use partial distal gastrectomy for distal lesions, partial proximal gastrectomy for proximal lesions, and total gastrectomy for widespread malignant lesions. The failure of removal of the antral mucosa in partial proximal gastrectomy may be alleviated by the performance of vagotomy, which is automatically done by the nature of the operation. Table II lists the operative mortality.

Eleven per cent of the entire group of patients did well on medical therapy. In 14 per cent the results were probably good, but these patients did not return for later follow-up studies. Twenty per cent did poorly, and refused surgery. In 58 per cent of the entire series surgical therapy was performed, and in 295 cases (all but 8) gastric resections were carried out, all but 4 of these were partial gastrectomies.

In these it appears that 75 per cent will be asymptomatic postoperatively, 15 per cent will have trivial symptoms amenable to dietary therapy, and 10 per cent will have symptoms of a small stomach, i.e., lack of appetite or gastric distress, and loss of strength, endurance or weight that will require medical care.

ERNEST D. BLOOMENTHAL, M.D.

On the Operative Treatment of Gastric and Duodenal Ulcer at the District Hospital Hämelenlinna, Finland KALEVA KORTTILA *Ann chir gyn fenn*, 1949, 38 Supp. 1

The present study shows that good primary and late results can be obtained by resection (Billroth II, anterior antecolic, and enteroanastomosis) in patients with chronic gastric and duodenal ulcers—the primary mortality being 3.2 per cent in the series of cases studied, and the late results good in 81.2 per cent of the cases.

There appeared to be no difference in the results obtained in cases in which a radical intervention was performed and the results in cases in which palliative operations (according to the method of Finsterer) were performed. With regard to the extent of the resection, a moderate resection seems to be the most advantageous.

During the period from 1946 through 1945 the total mortality following resection in Finland was 7.09 per cent, which percentage compares favorably with that reported for other Scandinavian countries.

In the treatment of perforating ulcers, a low mortality can be achieved by simple suture. In the present series of cases the mortality among patients with perforating ulcers was 14.1 per cent.

The author believes that since disturbances in gastric evacuation do not occur following simple suture, the performance of a gastrostomy, gastroenterostomy, or primary resection, for fear of this difficulty, is not imperative.

A good late result was obtained by simple suture in about 30 per cent of cases studied, and the condition of those patients whose symptoms persisted could be corrected by means of a secondary resection.

BENJAMIN GOLDMAN, M.D.

Benign Nonepithelial Tumors of the Stomach

JACOB RABINOVITCH, DAVID GRAYZEL, ALFRED J. SWYER, and BERNARD PINES *Arch Surg*, 1949, 58, 529

Twenty cases of benign nonepithelial tumors of the stomach have been observed at the Jewish Hospital of Brooklyn during the past 20 years. These tumors were as follows: 12 leiomyomas, 5 fibromas, 1 neurofibroma, and 2 lipomas.

There were no pathognomonic criteria manifested by these tumors. Among the 12 leiomyomas (60% of the cases), 10 were found incidental to operation or at autopsy. Their most frequent location was in the pylorus and they varied from 1.0 to 9.0 cm in diameter. Of the 5 fibromas none presented clinical evidence of a gastric neoplasm. None of these tumors exceeded 1.0 cm in diameter. The 1 neurofi-

SURGERY OF THE ABDOMEN

broma occasioned epigastric pain and hematemesis. The 2 lipomas were incidental findings at autopsy. During the same 20 year period, there were 11 cases of benign epithelial growths of the stomach and 9 cases of malignant nonepithelial tumors. Benign nonepithelial tumors of the stomach appear to be twice as common as benign epithelial growths and approximately 2 5 times as common as malignant connective tissue neoplasms.

FRANK B. QUEEN, M.D.

On Linitis Plastica and on Sclerosing Carcinoma of the Stomach (Carcinoma Disseminatum Krompecher, Carcinoma Fibrosum Konjetzny)
KAJ RØJEL. *Acta chir scand*, 1949, 97, 451

The author reviews the literature dealing with benign and malignant sclerosis of the stomach. The term "linitis plastica" has given rise to much obscurity, and the author suggests that its use be confined to benign sclerosis of the stomach. With regard to malignant sclerosis of the stomach, it is suggested that Krompecher's term, "carcinoma disseminatum" and Konjetzny's term "carcinoma fibrosum" be fused into the term "carcinoma disseminatum fibrosum."

The author reports 14 cases of carcinoma disseminatum fibrosum, the histological (and to some extent also the macroscopical) pictures of which are in conformity with the description given in the literature. Microscopically, carcinoma disseminatum fibrosum is characterized by the proliferating tumor tissue and by the reaction of the stomach to this process.

As far as the great majority of tumor cells are concerned, they can be included in, or constitute intermediary forms between, the following two types: (1) a small cell with a dense, often rod-shaped or slightly irregular nucleus rich in chromatin, and (2) a larger cell with a large round or ovoid vesicular nucleus poor in chromatin, often containing a nucleolus. In the protoplasm of some of these tumor cells, deposits of mucus can be observed. In the large cell type these deposits are most frequently in perinuclear arrangement and the nucleus is not displaced. In the smaller cell, the nucleus is displaced towards the periphery, so that signet-ring connections. The tumor cells have lost their epithelial connections and are isolated, in some cases lying separately, in others these cells occur in short rows, and in others they occur in small or larger clusters or strands, but always with a tendency to diffuse infiltration of the host tissue, they never display any formation of alveoli, cords, or glandular imitations. The reactive changes against the tumor tissue consist in mononuclear inflammatory infiltration, the formation of granulation tissue, and in the transformation of the latter into a shriveled, fibrous cicatricial tissue which is poor in cells. Lastly, the thickening and hyalinization observed in the muscularis mucosae must probably also be considered part of the reaction of the host tissue against the tumor infiltration. The macroscopical picture was typical of carcinoma dis-

seminatum fibrosum in 8 cases, the wall was more or less thickened, shriveled, and sclerosed, in some cases with distinct borders between its individual layers, and without localized tumor formations or callous ulcers. In 4 cases the macroscopical findings were described as cancerous ulcers, and in the remaining 2 cases the macroscopical description was too defective to allow of classification.

A brief reference is made to the clinical manifestations and the course of the 14 cases. The symptoms and the results of the laboratory examinations do not differ from those of cancer of the stomach in general. Two patients died immediately after the operation. Eight patients died 144, 60, 30, 24, 13, 13, 12, and 10 months after the operation. Four patients were still alive less than 2 years after the operation, but the author states that one of these patients is known to have suffered a relapse.

CHARLES BARON, M.D.

Clinical Notes Three Cases of Cancer of the Stomach Cured by Resection ALFRED R. PARSONS *Irish J. M. Sc.*, 1949, Ser 6, 179

Parsons comments on the increasing number of deaths from cancer during the period from 1937 to 1948. Although cancer deaths are lowest in Eire, cancer of the stomach is responsible for almost one-quarter of the total deaths from cancer in males, and for one-fifth of the total deaths from cancer in females.

Three cases of frank carcinoma are reported in which the tumor had attained a considerable size, nevertheless metastases had not occurred or at most had not passed beyond the glands of the lesser curvature. Stress is laid on the all importance of early diagnosis if successful resection is to be carried out. The 3 cases are the only examples of successful resection of the stomach for malignant disease in the author's clinical experience of over 50 years. The first case was that of a 30 year old patient who had progressive and unresponsive anemia, absence of free hydrochloric acid, and a palpable tumor. It is now 40 years since resection and the patient is enjoying remarkably good health. The second patient showed symptoms only 2 months prior to hospitalization and these pointed to a cardiovascular disturbance rather than a digestive disorder. On examination there was a palpable mass as large as an orange which was resected along with two-thirds of the stomach. The patient was doing exceptionally well 14 years after operation. The last patient had a large easily palpable tumor which lay concealed behind the costal arch. Partial gastrectomy was done September 6, 1934 and the patient is alive and well as of the present writing.

Commenting on these cases, Parsons concludes that the absence of hydrochloric acid in the stomach content is significant in the diagnosis of gastric carcinoma and the presence of a large mass does not necessarily indicate inoperability or a bad prognosis.

STEPHEN A. ZIEMAN, M.D.

A Preliminary Report on the Advantages of a Small Stoma in Partial Gastrectomy for Ulcer H W PORTER and Z B CLAMAN *Ann Surg*, 1949, 129 417

In a series of 118 partial gastrectomies for peptic ulcer, evidence was produced to show that a stoma 2.5 cm long has the following advantages

1 The small stoma with a Hofmeister-Finsterer valve reduces the risk of incidence of (a) leakage at the duodenal stump, (b) leakage at the anastomosis, (c) postoperative hemorrhage from the anastomosis, (d) the necessity for routine postoperative suction, and (e) jejunitis

2 The small stoma encourages (a) sphincteric action at the stoma, (b) delayed emptying time, and (c) the ability to eat a full normal diet at an early date, thereby shortening convalescence

3 The small stoma reduces the incidence of the dumping syndrome

JOHN J MALONEY, M D

Acute Obstruction of the Small Bowel F A COLLIER and R W BUXTON *J Am M Ass*, 1949, 140 135

The present study of acute bowel obstruction was made at the University Hospital, Ann Arbor, Michigan, and includes 198 patients observed during the years 1934 through 1947. In all cases the diagnosis was confirmed by operation or at autopsy. The high mortality rate (38.3%) is explained by the inclusion of cases of carcinoma in the series. The principal cause of death was peritonitis.

Eight patients who died because of leakage from the suture line following resection and anastomosis had had a side to side type of anastomosis. This type is particularly susceptible to failure because it cuts across the blood supply to the antimesenteric border of the bowel. One discussant mentioned the low incidence of leakage from the anastomosis when an oblique end to end type of anastomosis was performed.

The rate of successful small bowel intubation in this series was 68 per cent. Several cases of successful intubation were followed by perforation of the bowel at the site of the lesion. In mechanical obstruction, decompression by intubation was preliminary to surgical correction of the obstruction. In large bowel obstruction, decompression of the small bowel may result in an obstructed closed loop between the ileocecal valve and the lesion in the colon with possible perforation of the colon as a subsequent complication. Intubation from above seldom decompresses the colon and in these cases cecostomy is necessary.

Enterostomy, although generally condemned, was suggested to deflate a closed loop or, occasionally, in cases of long standing obstruction from multiple obstructions, to deflate the intervening obstructed loops.

Infection, with or without an associated factor of toxemia, is the commonest cause of death. Strangulation remains the most serious complication of obstruction.

Although the use of antibiotics, of long tube decompression, and the correction of dehydration and electrolyte imbalance have improved the outlook in cases of obstruction, early diagnosis of obstruction and of strangulation remain the most important factors in lowering mortality. If early diagnosis is coupled with prompt surgical intervention in those cases in which it is indicated, the mortality is still further improved.

Conservative management must be abandoned at once when (a) progressive decompression of the small intestine is not satisfactory within 36 hours after commencement of effective suction, (b) in the absence of a specific knowledge of the cause of the obstruction, temporary relief is attended by recurrence of the signs and symptoms of obstruction, and (c) the signs and symptoms suggest impairment of the bowel circulation or strangulation.

FREDERICK C HOEBEL, M D

Pneumatosis Intestinalis Roentgen Diagnosis and Surgical Management ALBERT I GAZIN, WALLACE S BROOKE, HENRY H LERNER, and PHILIP B PRICE *Am J Surg*, 1949, 77 563

Pneumatosis intestinalis is so little known that when it occurs it presents a challenge to diagnosis and management. The variations in degree and type, the discrepancy between the sparse clinical and the extensive operative findings, the diversity of pathologic conditions all invoke the exercise of keen judgment based on an appreciation of the fundamental nature of the disease.

Since pneumatosis is defined as the presence of gas in an abnormal location in the body, the diffuse spread of gas into the intestinal tissues is labeled pneumatosis intestinalis. The arrangement of this gas in cystlike accumulations within the wall of the intestine and its mesenteric attachments may be designated as pneumatosis cystoides intestinalis. This entity has been reported in the literature as "gas cysts of the intestine," "emphysema intestinorum," "cystic pneumatosis of the bowel" and "pneumatosis cystoides intestinorum hominis."

The first American report of a roentgenologic preoperative diagnosis of pneumatosis intestinalis is presented. The characteristic roentgenographic features are described.

The various etiologies of this entity are discussed and a theoretical concept of its development is presented. It is suggested that the process is as follows:

A break develops in the mucous membrane of the bowel, associated with some form of partial or complete obstruction of a part of the intestinal tract distal to this mucosal defect. The obstruction may occur from stenosis or adhesions. Because of the obstruction, hyperperistalsis takes place and forces gas out of the lumen of the bowel into the wall where it comes to lie either in the subserosal or the mucosal layers. The presence of the gas causes obstruction of the lymphatics and associated inflammatory changes. Normally the gas is reabsorbed. If, however, the

inflammatory and stenotic factions persist in the lymphatic system and become marked, absorption of the gas is blocked and the process becomes irreversible

The problem of conservative versus radical surgery in the treatment is raised. It is the opinion of the authors that the management of this entity demands a careful evaluation of the stage to which any given case has progressed. If the features of the case appear to be irreversible, radical surgery is indicated. In many cases simple relief of the obstruction may be sufficient. The case presented in this report is one in which conservative surgical management (lysis of adhesions) was tried at first, only to require the more radical procedure of extensive small bowel resection at a later date.

BENJAMIN GOLDMAN, M D

Malignant Tumors of the Small Intestine IRWIN E SIRIS *Am J Surg*, 1949, 77 573

The author presents 4 cases of malignant tumors of the small intestine. The underlying morbid process was different in each case. The difficulty in early recognition of tumors of this type, and the reasons for the grave prognosis are as follows: (1) the early symptoms are vague intermittent abdominal distress and distention bearing no relation to meals, followed by progressive weakness and severe anemia, (2) radiographically early, the disease is variously diagnosed and a correct radiographic interpretation is rarely made before the onset of partial obstruction, (3) with the onset of obstruction the disease is generally too far advanced to achieve a successful outcome, (4) the disease frequently extends to the mesentery which is foreshortened, (5) the lymphatic spread precludes radical extirpation of the inaccessible lymphatics, (6) metastasis and early recurrence within a few weeks to 2 years is to be expected if thorough extirpation of the involved lymphatics cannot be effected, (7) the disease is resistant to radiotherapy.

Extirpation of malignant tumors of the small intestine, even in advanced stages, is attended with a relatively low immediate operative mortality, therefore, earlier recognition of the disease may enhance the ultimate result. This may possibly be accomplished by (1) close evaluation of the history, (2) improvement in radiographic studies in order to ferret out the early intraluminary or extraluminary encroachments, and (3) comprehensive repeated laboratory investigations, particularly for occult blood in the stools and significant physicochemical changes in the blood in other than readily diagnosed entities.

BENJAMIN GOLDMAN, M D

The Management of Bleeding Duodenal Ulcers ROBERT W FRASER and JOHN P WEST *Ann Surg*, 1949, 129 299

The surgeon faces few therapeutic problems which are more perplexing than the management of a sudden, massive hemorrhage from a duodenal ulcer. When confronted with the individual case, statistics

do not provide the answer as to which course of treatment is most likely to lead to recovery. Without operation, the present mortality rate of 8 to 12 per cent (as variously reported) represents a distinct improvement over the mortality rate of 15 to 74 per cent of a decade ago, and appears to be largely due to the more generous use of blood transfusion since World War II.

There is no sure way of differentiating the fatal type of hemorrhage from the bleeding which will subside with nonoperative measures. Continuous recurrent, or sudden massive, hemorrhages occurring while the patient is under a strict medical regime are generally accepted as prime indications for surgical intervention. With a reliable bank and adequate blood replacement available, both the internist and the surgeon are allowed more time to plan the patient's therapeutic course, and this factor alone will undoubtedly result in improved mortality figures for both the operative and nonoperative cases.

The authors have reviewed the records of 177 cases of severe hemorrhage from duodenal ulcers. In all patients, the diagnosis was established by roentgenography, at operation or at autopsy, and the criteria for severe bleeding was a drop in hemoglobin to 65 per cent or less, and a reduction in red cells to 3,500,000 or less. One hundred and sixty-five patients were treated by nonoperative measures with 7 fatalities, a mortality rate of 4.2 per cent. Twelve patients did not show a satisfactory response to conservative treatment, and were operated upon while actively bleeding. All were operated upon in the late period, that is, after more than 48 hours of rapid blood loss, and 4 patients died, a mortality rate of 33.3 per cent. Ninety-three of the total series of patients were under 50 years of age, 9 of these were operated upon with 3 deaths, but there were no deaths in the group of 84 patients treated without operation. Eighty-four patients of the total series were over 50 years of age. Of these, 81 patients were treated by nonoperative measures, with death of 7, and 3 patients were operatively treated, with death of 1 patient.

The authors conclude that the occasional indications for surgical treatment of bleeding duodenal ulcers are limited, with few exceptions, to patients over 50 years of age. Operation apparently saved the lives of 4 patients in this series, but at the same time it appears probable that some of the patients subjected to operation might have survived without surgical intervention.

WAYNE FIELD CAMERON, M D

Two Cases of Persistent Jejunitis Following Partial Gastrectomy J L STEPHEN *Brit J Surg*, 1949, 36 325

Two cases are described in which chronic jejunitis followed partial gastrectomy. Antecolic retroperistaltic gastrectomy of the Hofmeister type was done in both cases, but it is noted that in 246 other gastrectomies, 148 of which were done according to the same procedure, no other similar case was en-

countered. Both patients complained of persistent diarrhea and rather vague tenderness down the left side of the abdomen. The diarrhea was characterized by a loose bowel movement after nearly every meal and was checked only by repeated small doses of bismuth and opium, sulfasuxidine, even in large doses, had had no effect. The tenderness on the left side corresponded in position to the first 20 cm. of the jejunum below the gastric stoma as seen on barium meal screening. No ulcer or special point of tenderness could be found. In neither case were pathogenic organisms found in the stool.

Both patients have been otherwise improved by the operation, have maintained their original weight, and have been able to continue with their previous work. The author believes that the condition is an extension of a pre-existing gastritis.

JOHN L. LINDQUIST, M.D.

Polypoid Lesions of the Terminal Portion of the Colon. LOUIS A. BUIE, NEWTON D. SMITH, RAYMOND J. JACKMAN, and JOHN R. HILL. *J. Am. Med. Ass.*, 1949, 139: 702.

Knowledge of the pathologic manifestations and of the diagnosis of polypoid disease of the colon has progressed, but results of treatment of the condition still are discouraging. Fulguration (which the authors define as a nonsurgical procedure) is described and reasons for its use are given. Also, how the proctologist can aid in combating this grave disease is outlined.

Polyps may occur singly or in numbers, and they may be sessile or pedunculated. The entire colon may be involved by polypoid disease, there are grossly two types of this condition. In one type, the polyps are discrete and gross evidence of pathologic change in the intervening tissues is absent. In the other type, there is a diffuse hyperplastic involvement, which may be segmental or total, and many polyps of all types, sizes, and shapes are found. Often, no part of the wall of the colon is free from disease. Such complete involvement is important and must be evaluated in relation to treatment.

The authors urge periodic examination of all patients who have had polypoid lesions of the terminal portion of the colon. The frequency of examinations depends on the seriousness of the condition. Roughly speaking, examination in from 1 to 3 months after completion of treatment is urged for all patients whose lesions were 1 cm. or more in diameter. There is more need for the examination if the lesion was sessile than if it was pedunculated. Regardless of the size of the lesion, it is not recommended that examination be deferred longer than a year. Roentgenologic examination of the colon never should be overlooked in cases in which polyps are found in the course of proctoscopic examination.

The term "fulguration," as the authors employ it, designates a procedure intended to destroy a growth by means of an electric spark which emanates from the electrode of a monopolar (Oudin) current. A bipolar current may be used. While a lesion is being

fulgurated, the tip of the electrode should be held so that the spark will leap approximately 5 to 6 mm. from the electrode to the surface of the growth. In this manner, the superficial layers of the polyp are first dried and later charred. Soon, an actual flame extends between the tip of the electrode and the tissues. After fulguration has been completed, a charred mass of tissue replaces the polyp. Fractional fulguration for indefinite periods may be necessary in order to destroy large lesions. In the case of pedunculated lesions, the site of attack may be the junction of the polyp and the pedicle. If this juncture cannot be exposed, and sometimes even if it can, and the polyp or pedicle is large, the body of the polyp should be fulgurated. Care must be exercised when fulgurating a pedicle, because often the pedicle carries a large artery. Sometimes, also, the peritoneal surface of the bowel wall is drawn into the pedicle.

A proctoscope which is suitable for use while performing fulguration includes a built-in suction tube through which smoke and gas can be exhausted from the bowel during fulguration. If such suction is not available, gas within the bowel may ignite or explode. Also, a means must be provided for exhausting stool and fluids from the bowel. The surface of the lesion must be kept dry during fulguration.

In most instances, anesthesia is not necessary or desirable. General anesthesia never should be employed. When the lesion is close to the anus or actually involves it, or when adequate exposure cannot be obtained, caudocranial anesthesia may be employed.

Complications of the procedure are rare.

Fulguration is an effective method, but great care must be used when selecting patients for this type of treatment.

Usually a pedunculated polyp may be fulgurated, regardless of its size or position in the bowel, provided that adequate exposure of the polyp and the entire pedicle can be obtained.

Large sessile polyps require more careful consideration. If such a polyp must be fulgurated, the ideal situation for it is on the posterior wall of that portion of the rectum which is not covered by mesentery. In that location there is little danger of injuring a vital structure, should it be considered necessary to destroy the wall of the bowel during the process of fulguration.

Malignant lesions deserve even more serious consideration than that which is given large sessile polyps. In order for treatment of these lesions to be at all successful, that portion of the wall of the bowel to which the growth is attached must always be destroyed. Consequently, such lesions should not be attacked by fulguration unless they involve the posterior wall of the rectum and only that portion of the rectum which lies distal to the peritoneal reflection. It is possible that malignant lesions which are not so ideally situated may respond favorably to fulguration, but they should not be so treated unless proper radical surgical measures are contraindicated or are rejected by the patient.

SURGERY OF THE ABDOMEN

Large disseminated polypoid lesions, whether benign or malignant, and those which are associated with diffuse hyperplasia of the mucous membrane respond poorly to fulguration, either when it is used alone or in conjunction with radium therapy. Radical surgical treatment is indicated in such cases. In fact, the same attitude should be adopted in regard to such conditions as that which is maintained in connection with the management of malignant disease.

Complete Excision of Pelvic Viscera in the Male for Advanced Carcinoma of the Sigmoid Invading the Urinary Bladder

ALEXANDER BRUNSCHWIG
Ann Surg, 1949, 129 499

Brunschwig narrates in detail a case of complete excision of pelvic organs in a male for an advanced carcinoma of sigmoid which was found to be invading the urinary bladder. The patient was able to return to his usual occupation with relief from pain and episodes of chills and fever of urinary tract origin with complete recovery in 14 months after operation. The case illustrates how certain abdominal neoplasms may progress locally to a marked degree before liver metastasis becomes manifested and, moreover, it shows the feasibility of complete excision of pelvic viscera in the male as a counterpart of the procedure devised for advanced pelvic cancer in the female.

STEPHEN A. ZIEMAN, M.D.

The Selection of an Operative Procedure for Patients with Lymphogranuloma Venereum of the Rectum

LESTER BREIDENBACH and LOUIS R. SLATTERY
Surg Clin N America, 1949, 29 399

The authors state that while the simplest surgical treatment of rectal strictures caused by venereal lymphogranuloma is excision of the rectum by the abdominoperineal technique of Miles, they prefer a surgical method that eliminates the stricture and preserves sphincteric function. Thus, they pushed the frontiers of surgical therapy for this crippling inflammatory rectal lesion far ahead of its place at the time they tackled this problem.

Usually, most of these patients do not present themselves for treatment until the disease is far advanced. The local pathologic changes consist of a tubular stricture involving the rectal ampulla for varying distances proximally and may be accompanied by fistulas to the perianal skin. Under such conditions, definitive or palliative local surgical procedures are contraindicated, the first objective being the institution of complete diversion of fecal stream and complete rest for the involved portion of the terminal bowel, which is accomplished by a defunctioning colostomy. A right-sided transverse colostomy is performed by completely dividing and separating the transverse colon through a transverse incision and implanting the end of each loop at each angle of the wound. The abdominal wall is closed in layers between the 2 stomas, and internal herniation is avoided by including the raw edge of the mesocolon in the peritoneal closure. This colostomy is closed intraperitoneally by freeing, and end-to-

end anastomosis of, the severed ends of the bowel. The authors consider this type of closure safer than the blind procedure which involves crushing of spurs.

The preliminary, temporary colostomy relieves chronic obstruction and allows the infection to subside. Since it is believed that gain in weight by the patient is the most accurate index of general improvement, the authors allow their patients to regain, or even exceed, their normal weight. Complete nutritional rehabilitation of the patient and control of the regional infection is accomplished in several weeks or months.

Roentgenographic studies through the distal colostomy and rectum determine the extent of involvement and influence the decision as to whether the strictured area may be removed by the perineal route alone or by the abdominoperineal routes. The status of the anal canal determines whether a low intestinal anastomosis or a "pull-through" procedure will be possible. Disease of the anal canal and perianal strictures calls for a "pull-through" operation, as described by Wright, while a normal anus and a terminal 3 cm. of rectum permit the re-establishment of intestinal continuity by anastomosing the bowel above the mucocutaneous junction. Sacral exposure through a y-shaped incision permits access to those strictures that are limited to the rectal ampulla, but is inadequate for mobilization of the rectosigmoid or sigmoid. For the latter, the abdominal approach is necessary. Mobilization of the normal sigmoid for restitution of continuity is possible only by performance of a laparotomy. After freeing of the stricture and mobilization of the normal bowel, the abdomen is closed, the patient is then placed in the prone position and operation is continued through the perineal approach. The authors state that preservation of the anal canal gives more satisfactory sphincteric control than the pull-through procedures.

Extensive involvement of the left colon, either in continuity or segmentally (skip areas), pose a difficult therapeutic problem. After excision of large segments of the left-sided colon, considerable normal colon above the area of involvement must be mobilized to re-establish continuity. When the inferior mesenteric artery must be sacrificed, the proximal colon is mobilized with great care to preserve the marginal artery through which adequate blood supply is maintained by its anastomosis with the left branch of the middle colic artery. The mobilized segment of the bowel can be anastomosed to the rectum just above the anal canal or pulled through.

Only palliative procedures are indicated in a small number of elderly patients.

The preoperative and postoperative care is discussed briefly, it is essentially similar to that for colonic resection for the treatment of cancer.

The authors describe their results with 21 patients after the elimination of the strictured area and the restoration of intestinal continuity. There have

been 17 good results, one fair and one undetermined result, and 2 failures. The result is considered good when there is good sphincteric control without evidence of disease. The result is considered fair when there is narrowing of the bowel following surgical intervention in the presence of good sphincteric control. One failure resulted from sloughing of the bowel after it had been pulled through the sphincters under tension. Another patient had prompt recurrence of the disease after insufficient resection, and this patient was successfully reoperated upon after the reappearance of the granulomatous process at the site of the anastomosis. No deaths occurred in the group of 21 patients in whom intestinal continuity was re-established. Death occurred in 2 other patients, one acutely ill patient died following colostomy, while the other patient died following revision of a loop colostomy.

ROBERT TURELL, M D

Operative Treatment of Carcinoma of the Distal Colon and Rectum SAMUEL STANDARD and JOHN H MULHOLLAND *Surg Clin N America*, 1949, 29: 323

When dealing with carcinoma, the authors believe that the rectum "proper" should be separated from the lower sigmoid and the rectosigmoid. Difficulty in delineating the exact boundaries of the rectosigmoid could be eliminated by including that portion of the bowel which is completely covered by peritoneum. It is the authors' present policy to remove tumors of the lower sigmoid and rectosigmoid by anterior resection and primary anastomosis, which is defined as a surgical procedure in which it is necessary to mobilize the rectum from the hollow of the sacrum in order to achieve the anastomosis. This practice will eliminate colostomy in more than one-third of the patients now being treated by abdominoperineal resection.

Tumors of the rectum proper are divided into 4 groups:

1 Tumors situated from 1 to 3 inches (2.5 to 7.5 cm) from the anus, which require abdominoperineal resection.

2 Tumors situated from 3 to 5 inches (7.5 to 12.5 cm) from the anus which should be treated by abdominoperineal resection if they are large, if the fascia propria is involved, or if there is attachment to the adjacent pelvis. On the other hand, if the tumor in this area is small in size, localized, does not penetrate through the serosa, and can be removed with 3 to 5 cm (1+ to 2 inches) of rectum below the edge of the neoplasm, it should be extirpated by anterior resection.

3 Tumors that are situated 5 inches (12.5 cm) above the anus and which should have the preference of anterior resection and primary anastomosis if they are locally resectable. Only in cases of advanced lesions should abdominoperineal resection be performed.

4 Tumors, regardless of their location, when associated with incurable metastases and which should

be accorded the operation of anterior resection whenever it is technically feasible, because cure is no longer a consideration.

The authors report their experience with 40 anterior resections. In this series, the location of the tumors ranged from 3 to 10 inches (7.5 to 25 cm) above the anus. Earlier in their experience the tumors situated at lower levels were also removed by this procedure. Two of their patients died, one on the fifth and the other on the sixth postoperative day. Five of the 40 patients had had hepatic metastases at the time of operation. Four of these patients lived from 4 to 8 months and had normal bowel movements. The fifth patient was alive 10 months after operation at the time this article was completed. Five patients required resection of other organs because of adherence. Two patients required decompressing colostomy for acute obstruction on admission to the hospital. No proximal colostomy had been performed at the time of the primary operation. In one case the omission of the construction of a proximal vent was admittedly an error of surgical judgment. The authors believe that routine proximal colostomies are unnecessary, but that they should be done when a doubt exists about the viability of the anastomotic edges or about the adequacy of the suture line. There were 3 complicating fistulas in this series of cases, one drained sacally and closed in 34 days, another drained abdominally and closed in 12 days, and the third one failed to heal and was found to originate in a recurrence at the site of anastomosis. A bladder injury was repaired and healed uneventfully. No impotence was observed in 2 men aged 37 and 47 years, respectively. In 3 early cases the neoplasm was situated too close to the anus and at the present time the patients are being treated by abdominoperineal resection. None of the recovered patients have developed strictures at the site of the anastomosis.

The preoperative and postoperative preparation as well as the technique of anterior resection with primary anastomosis are recorded in detail.

The authors put into the general group of colonic tumors any lesion in the sigmoid which can be removed with a sufficiently wide margin of healthy colon without mobilization of the rectum from the sacrum. For these, resection and primary anastomosis has been done during the past 5 years. Neither the original or the modified Mikulicz procedure nor the Lahey two-stage abdominoperineal resection is now utilized.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Internal Biliary Fistulas EARL E BARTH and ABRAM H CANNON *Q Bull Northwest Univ M School*, 1949, 23: 8

Although the presence of a fistulous connection between the biliary tree and the abdominal viscera is considered a rare occurrence, the true incidence is believed to be higher than is generally supposed.

SURGERY OF THE ABDOMEN

There is nothing in the clinical picture which will unequivocally establish the diagnosis, although in many cases roentgen examination of the abdomen may suggest the diagnosis, and at times definitely establish the diagnosis of internal biliary fistula by the demonstration of gas or barium in the biliary tree. Since these fistulas are usually buried in dense adhesions they are difficult to recognize at operation or at autopsy. The true incidence is difficult to ascertain further because the fistulas close spontaneously when the exciting factor has been relieved.

Almost all the intra-abdominal organs have been involved in biliary fistulas, although the vast majority of fistulas consist of an abnormal tract between the gall bladder and the duodenum. The cholecystocolic, choledochoduodenal, and the cholecystogastric types are next in incidence. Gallstones are the primary initiating factor in fistula formation. As a result of the accompanying cholecystitis, adhesions are formed between the gall bladder and adjacent viscera, and during an acute attack a fistula results from the necrotizing action of the gallstone or an associated empyema. A concurrent obstruction of the common duct, usually by an impacted stone, is an important factor in the production of fistula. Penetrating peptic ulcers account for about 6 per cent of spontaneous fistulas. Usually the ulcer is situated on the posterior wall of the duodenal bulb and perforation occurs into the common duct. Gastric ulcer, or cancer of the stomach, pancreas, or common duct may produce fistulas.

Emphysematous cholecystitis may simulate an internal biliary fistula, but the absence of gas in the bile ducts, the symptoms of acute cholecystitis, and perhaps some pericholecystic extension of the gas should serve to differentiate these two entities. Lipomatosis of the gall bladder may produce a superficial radiolucency of the gall bladder but no outline of the bile ducts will be seen, and the central part of the gall bladder shadow will have its normal density. Other causes of error in the differential diagnosis are the presence of barium beyond the duodenal wall in perforated ulcer, large duodenal diverticula which may simulate a gall bladder filled with barium, or reflux of barium through a dilated sphincter of Oddi.

The authors emphasize that in patients with obscure symptoms referable to the gall bladder, a scout film may afford evidence of gas in the biliary tree which will lead to the correct diagnosis.

WAYNE FIELD CAMERON, M D

The Role of Roentgenology in the Prevention and in the Diagnosis of Postoperative Pain Syndromes in Cholecystectomies (Il compito della radiologia nella prevenzione e nella diagnosi dei postumi della colecistectomia) GIUSEPPE MUSCETTOLA *Gior ital chir*, 1949, 5 73

The author's discussion of possible causes for the occurrence of failures and pain syndromes following cholecystectomies, considered from the roentgenologic standpoint, is supplementary to that by the surgeon, Imperati who presented the surgical aspects

of the problem (*Gior ital chir*, 1948, 4 479 and 547). From a study of the literature on the subject, most of which has already been discussed in the above cited article by Imperati, and a consideration of his own experience, the author offers certain conclusions peculiar to the field of roentgenology.

It is believed that in the cholecystopathies, especially those in which cholecystectomy is generally indicated, a roentgenologic examination (when coordinated with the clinical picture, and performed in a technically correct and adequate form) is valuable not only as a preoperative diagnostic and orientative surgical measure, but also as a means of forestalling the painful sequelae which so plague the surgeon in dealing with the biliary tract.

With reference to the per-operative roentgen manometry practiced so intensively by the Lyon-naise school of French surgeons (Pierre Mallet Guy, René Jeanjean, and Pierre Marion), it is recognized that the surgery of the biliary tract has been essentially advanced by this technique. The author frankly admits that his own experience with this method has been meager, and he does not wish to imply that he thinks the French surgeons are overly enthusiastic, however, from a study of their reports and conclusions, he believes that a certain amount of caution in appraising the results to be anticipated in the use of the per-operative procedure is justified. Its lack of precision and variability would seem to diminish its value in the study of functional disturbances of the biliary tract in general. The difficulty of precision in its application to the study of the cholecysticus and of the cystic duct suggests caution in the interpretation of its findings in this portion of the biliary canal. The chief value of the method would seem to lie in its application to the study of cases of lithiasis, of inflammation and of stenosis (both intrinsic and extrinsic) of the choledochus, hepatic ducts, and intrahepatic biliary branches. The limitations and the inconveniences of the method would seem to suggest considerable caution in the choice of patients for its application.

The most frequent causes of recurrences and of pain syndromes, as brought to light by roentgenology, are the unrecognized and unremoved bile stone, the associated inflammatory affections of the bile tract and of associated organs (pancreatitis, periangiocholitis, hepatitis), the accompanying—perhaps preoperatively unrecognized, or incompletely recognized—pain syndromes of other abdominal organs (duodenitis, peptic ulcer, appendicitis), and the diffuse adhesion syndromes of the right side of the abdomen (periduodenitis, pericholecystitis, ascending adhesive processes originating in the appendix), all of which may have been present before the operation and, on occasion, aggravated and extended by the operation itself.

In these postoperative syndromes of pain caused by a process of adhesions, a protracted course of Marconi therapy, associated with small doses of roentgen therapy may give valuable assistance.

JOHN W BRENNAN, M D

The Surgical Treatment of Pancreatitis HENRY DOUBILET and JOHN H. MULHOLLAND *Surg Clin N America*, 1949, 29: 339

The authors believe that pancreatitis is a common disease varying in intensity from mild attacks to severe abdominal catastrophes. Recurrent pancreatitis is frequently confused with the postcholecystectomy syndrome or biliary dyskinesia. An understanding of the etiology and pathology of recurrent acute pancreatitis and its sequelae helps one to diagnose and treat this condition rationally by definitive surgery.

The salient experimental and clinical observations are enumerated and briefly discussed. Cholangiographic studies conducted by the authors point to reflux of bile into the pancreas as a predominating etiologic factor. This reflux is frequently brought about by abnormal spasm of the sphincter of Oddi in the presence of a common biliary pancreatic passage-way above the sphincter.

The correct diagnosis during the acute attack is frequently difficult to make as during the height of the attack this condition may closely resemble a perforating peptic ulcer, acute cholecystitis with or without perforation, acute intestinal obstruction, mesenteric thrombosis, or cardiac infarction. The estimation of the serum amylase values is of real help in the differential diagnosis. A high serum amylase value suggests acute pancreatic disease, however, a low value does not always exclude pancreatitis, especially if the test is done several days after the onset of the disease. In spite of its limitations, the serum amylase test should be performed in all acute upper abdominal conditions.

The outstanding characteristics of the interval phase of recurrent acute pancreatitis is pain after eating and the loss of weight due to fear of eating. There is usually an absence of a high serum amylase level even during an attack which lasts 2 or 3 days. Under these circumstances, the secretin test assumes great value. A diminished flow of pancreatic juice in response to a standard dose of secretin is of diagnostic importance. It should be kept in mind, however, that frequently the secretin test falls within normal limits. A diminished concentration of bicarbonate or a very low concentration of amylase in the pancreatic juice is indicative of pancreatic disease.

The treatment of the acute phase of pancreatitis is nonsurgical. Dehydration and shock are treated with intravenous fluids, blood, and plasma. Complete rest of the alimentary tract is instituted. Antispasmodic drugs, such as atropine in dosages of 1-3 mgm (1/150 gr) and papaverine in dosages of 120 mgm (2 grains) are given every 4 hours. It should be recalled that these drugs may be ineffectual when the sphincter of Oddi is rendered spastic by inflammation. The administration of penicillin, 300,000 units every 6 hours, will help to prevent infection of the necrotic pancreatic tissue and exudate. These therapeutic measures plus supportive therapy are kept up continuously until the patient improves and the serum amylase test, performed

daily, has returned to normal levels. When the patient has recovered and is able to walk, other diagnostic studies, such as roentgenography, secretin test, sugar tolerance curve, and so forth, are instituted.

The operation is performed about 3 weeks later. The operative technique of endocholedochal sphincterotomy is described in detail. Allusion is made to the difficulties that may prevent section of the sphincter of Oddi. Considerable reliance is placed on the cholangiogram for the delineation of the size, direction, and tortuosity of the common duct. Sphincterotomy is said to cure the patient and will prevent further attacks of pancreatitis.

ROBERT TURELL, M.D.

Cystic Fibrosis of the Pancreas J. HOWARD and L. HESSELVIK *Uppsala läk fören förh*, 1949, 1: 53

Cystic fibrosis of the pancreas is a congenital disease characterized by the total absence or gross deficiency of the external pancreatic secretion, resulting in symptoms referable to the digestive or respiratory systems, or both. These symptoms are present at birth or manifest themselves during the first year of life.

The distribution of the disease is world wide. There is no sex predominance, and in approximately 50 percent of the cases it occurs as a familial disease.

The many theories as to the cause of the disease can be reduced to five leading ones: (1) obstruction of the large and small pancreatic ducts, which in some cases is on the basis of atresia, (2) inspissated secretion, which may be on the basis of a disturbance of parasympathetic innervation, (3) avitaminosis A, which leads to desquamation of ductal epithelium and subsequent mechanical blocking of the ducts, (4) fibrosis following inflammatory change, (5) Glanzmann's theory, which states that antibodies similar to the Rh antibody pass by way of the aspirated amniotic fluid into the lumens of the intestine, lungs, and pancreas and there react with local cellular antigens, thus injuring the developing glands.

The authors believe that in those cases in which there is no atresia of the ducts an imbalance of the nervous control of pancreatic secretion is the most plausible theory of etiology.

The chief pathologic findings in early life are dilatation of the acini and smaller ducts, and the presence of eosinophilic concretions blocking their lumens. The number of acini remains normal, and there is a marked proliferation of fibrous tissue. In older infants, the atrophic acini are replaced by fat. Thick inspissated meconium blocks the intestinal tract. The commonest lesion in the respiratory tract is a tracheobronchitis.

The clinical picture usually fits into one of three groups: (1) cases with meconium ileus, (2) cases with onset of a respiratory infection before the sixth month, (3) those with onset of respiratory symptoms after 6 months.

The most significant laboratory finding is the demonstration of the absence of, or greatly decreased,

trypsin content in the duodenal juice. The diagnosis of cystic fibrosis of the pancreas cannot be correct if there are normal amounts of trypsin. Other pancreatic enzymes in the duodenal juice are also diminished. Steatorrhea is present to some degree, and this may be demonstrated by microscopic or chemical analysis of the stool.

Röntgenographic examination of the lungs generally is negative at birth. Later, obstructive emphysema or localized patches of atelectasis may be demonstrated. Röntgen examination of the intestinal pattern may show clumping of barium as it does in other subgroups of celiac syndrome.

Treatment of the disease is based on two principles: first, the nutritional condition of the patient must be corrected, and second, measures must be taken to control the respiratory infection. The diet for these patients should be high in calories to remedy the poor food utilization, it should contain twice as much protein as is usually prescribed for the patient's age, it should be rich in carbohydrates, but no starch should be given until after the third year, a low fat intake is important, vegetables and fruits are well tolerated, vitamins, especially A and D, should be given. Pancreatin sometimes produces striking results.

Penicillin orally, intramuscularly, and by nebulization has been used for the respiratory stages of the disease. Streptomycin has not yet had an adequate trial.

Fourteen years is the longest survival for an untreated child with cystic fibrosis of the pancreas. Most children survive about 2 years if untreated. Surgery is the only hope for infants with meconium ileus, and even with successful surgery the condition is apt to recur. Penicillin has improved the prognosis of those with severe respiratory disease. If the disease is diagnosed early and given adequate treatment, the child has a fairly good chance of reaching adulthood.

Case reports of 7 carefully studied cases are given. Three patients died. Four patients were treated medically, but satisfactory control of the condition was obtained in only one.

FREDERICK W. PRESTON, M.D.

Indications and Results of Left Pancreatectomy

Report of 16 Cases (Indications et résultats de la pancréatectomie gauche, d'après 16 observations personnelles). P. MALLAT GUY and R. LACOUR. *Lyon chir.*, 1949, 44: 169.

Left pancreatectomy consists of mobilization of the pancreas and resection of all of the gland to the left of the midline, and usually all of the gland except that portion adjacent to the duodenum. Indications for the operation in 16 cases included 1 patient with benign tumor, 1 patient with hyperinsulinism, 12 patients with inflammatory disease, and 2 patients with malignant disease of the pancreas. There was 1 operative death. Postoperative complications included postoperative hemorrhage, pseudocystic degeneration of the pancreatic remnant, infection in

the remnant, and persistent fistula. Each occurred in one patient.

For lesions localized in the left portion of the pancreas, the operation is preferable to marsupialization or to enucleation. The exception to this statement is adenoma of the islands of Langerhans. Occasionally these adenomas can be palpated as discrete lesions and, if so, an enucleation may be done. If the adenomas are multiple, left pancreatectomy, left and right pancreatectomy, or total removal of the gland may be indicated, depending upon the extent of the lesion.

The treatment of acute pancreatitis by pancreatectomy was abandoned by most surgeons many years ago. However, the authors cite one case in which an acute hemorrhagic pancreatitis was complicated by persistent bleeding. The bleeding was stopped and the patient was cured by left pancreatectomy.

Four patients with chronic pancreatitis who had recurring attacks of acute pancreatitis were subjected to left pancreatectomy, with good results.

The operation had also been tried for patients with severe pain caused by chronic relapsing pancreatitis. However, the most effective treatment introduced to date for these patients is unilateral splanchnic nerve section.

Occasionally when calculi are present in the duct of Wirsung, the treatment of choice is left pancreatectomy. Simple extraction of these stones is often impractical because of the multiplicity of the calculi, and often the procedure is unsuccessful because of persistent external pancreatic fistula. If calculi are present in the head of the pancreas, left pancreatectomy may be combined with right pancreatectomy or with pancreaticolithotomy. Two of the authors' patients who were subjected to left and right pancreatectomy for calculi obtained excellent results.

Carcinoma of the pancreas usually cannot be cured by any operation short of total pancreatectomy. In 2 of the authors' cases left pancreatectomy was done for pseudocyst, and on histologic study carcinoma was found to be present. In one of these patients the carcinoma promptly recurred, the other, who is still alive, is one of the few patients with carcinoma of the pancreas ever cured by this operation.

FREDERICK F. PRESTON, M.D.

Present Concepts in Surgery of the Spleen. LOUIS M. TOUSSELOT. *Surg. Clin. N. America*, 1949, 29: 369.

The author stated that the surgical treatment of splenopathies has been changing in the past few years. Generic terms of only a decade ago are being broken down into less ambiguous and more definitive groups.

Splenectomy is indicated in the following conditions: (1) carcinoma of the stomach, colon, or pancreas (it is used as an adjunct to other surgery in these conditions, also, pancreatic resection for hyperinsulinism may so compromise the splenic vein that splenectomy is inevitable); (2) anomalies; (3) rupture, traumatic or spontaneous, unrelated to trauma; (4)

hemolytic icterus, the congenital or acquired forms, (5) idiopathic purpura hemorrhagica, and (6) congestive splenomegaly (portal hypertension)

All aspects of hemolytic icterus, including the value of a new diagnostic blood test used to differentiate the congenital from the acquired types, are discussed. Considerable discussion is also devoted to portal hypertension (congestive splenomegaly) with an allusion to the couplings that have been described to date by various surgeons. The one stage splenectomy with portacaval shunt is advocated for the treatment of this condition.

ROBERT TURELL, M D

MISCELLANEOUS

Multiple Aortointestinal Fistulas Secondary to Swallowed Foreign Body JOHN D. HOLLE.
Surgery, 1949, 25: 608

A single case of aortoduodenal fistula which was secondary to a swallowed needle is presented as a case report.

A 21 year old white male had complained of gastrointestinal tract bleeding for 6 weeks. The patient was very thoroughly examined from the gastrointestinal and laboratory standpoint. A Sippy diet and blood transfusions were the principal treatment. An exploratory laparotomy was essentially negative. Mas-

sive hemorrhages continued. The patient was again prepared, and a second laparotomy was performed. On this occasion a sharp, pointed object was encountered in a third portion of the duodenum beneath the superior mesenteric vessels. Re-examination of the x-ray films showed a sewing needle which had been present but disregarded in all previous x-ray examinations. A pulsating aortointestinal fistula extended from the abdominal aorta to the posterior wall of the duodenum. This was excised. The needle was lost. X-ray re-examination showed the needle to be one vertebra lower than previously. The patient received a total of 26,500 c.c. of whole citrated blood and 1,200 c.c. of pooled plasma. He was discharged from the hospital and after a period of 4 months he began to pass blood. A fourth laparotomy was performed. This time a pulsating mass was found over the distal portion of the abdominal aorta which measured 9 cm. in diameter. A false aneurysm and two loops of ileum were resected. Part of the needle was removed. The patient made an uneventful recovery. Another x-ray revealed a $\frac{1}{2}$ cm. fragment of the needle still present. Three months following his last discharge he again passed bloody stools. A fifth laparotomy was performed. Two months following this last laparotomy he appeared to be well with the fragment of the needle still present.

GYNECOLOGY

UTERUS

Complications of Endometriosis CLYDE L. RAN
DALL *J Am M Ass*, 1949, 139 972

Complications of endometriosis are disturbances resulting whenever disseminated superficial lesions or a single penetrating nodule interferes, symptomatically or mechanically, with the function of the reproductive, urinary, or digestive tracts. Often there seems little correlation between the severity of the symptoms and the extent of the disease. Menstrual irregularities are not often due to the disease.

Endometriosis frequently gives rise to pain which is aggravated at the time of the menses but, like pelvic inflammation or neoplasm, it tends to recur throughout the month. Frequent as menstrual pain may be, a history of dysmenorrhea warrants the suspicion of endometriosis in cases in which the patient describes a classic and progressive "acquired" type of pain.

Dyspareunia can be relieved only by eradication of the responsible implants.

The evidence suggests that the development of endometriosis is favored by infertility. Endometriosis does not regularly interfere with ovulation, and it does not close the genital tracts and actually prohibit conception. Existing foci of endometriosis undergo noticeable resolution during pregnancy.

Although digestive disturbances are rarely due to endometriosis, the rectosigmoid, and occasionally other areas, may be involved. When the former is involved, the symptoms and signs may simulate those of diverticulitis or cancer of the bowel.

Urinary distress is not often due to endometriosis, but bladder function and the caliber of the lower ureter may be affected by the disease.

Roentgen irradiation in subcastration dosage is of little value. However, when castration is permissible, surgical treatment can be avoided by roentgen treatment.

At the present time it is difficult to evaluate endocrine therapy, and further investigation is indicated.

In surgery for endometriosis dysmenorrhea, thorough exploration and adequate resection of the involved tissues are important. If the uterus and any ovarian tissue are to be preserved, a presacral nerve resection is necessary.

Although castration avoids further progress of the disease, gynecologists have recommended resection of the ovaries rather than oophorectomy, with the result that pregnancy has resulted in at least one-third of the patients. However, reoperation may be necessary in at least 30 per cent.

Endometriosis of the rectosigmoid must be differentiated from carcinoma. Castration accomplishes symptomatic relief in endometriosis of the bowel.

Implants producing cul-de-sac adhesions often infiltrate the muscularis of the bowel wall and extend retroperitoneally along the parametrium until the induration makes the uterosacral region rigid and, occasionally, the ureter is compressed. In such circumstances, castration or extensive retroperitoneal dissection is necessary to relieve the patient, and either procedure proves effective.

T FLOYD BELL, M D

Surgical Treatment of Endometriosis CLAYTON T BEECHAM *J Am M Ass*, 1949, 139 971

As observations on the behavior of endometriosis increase, the indication for surgical treatment declines. Pregnancy is the best therapeutic measure. However, there are limitations of, as well as failures in, nonoperative medical and hormonal treatment of endometritis.

The author reports an incidence of endometriosis of from 5 to 8 per cent in his series of patients. One-half of the cases were successfully managed without operation.

The following conditions are indications for surgical treatment after failure of medical therapy: (1) dysmenorrhea, (2) pain in the lower quadrant of the abdomen, (3) dyspareunia, (4) menorrhagia, (5) rectal pain and tenesmus, and (6) metrorrhagia.

Surgical procedures must be carefully individualized. The important factors that will aid the surgeon in the selection of a given procedure are: (1) the age of the patient, (2) her marital status, (3) the number of children she has borne, (4) infertility, (5) acceptance of a conservative policy as regards the operation and what it might mean in the event of failure to relieve all the symptoms, and (6) the emotional balance of the patient.

Any patient, regardless of age, with symptoms of partial bowel obstruction from endometriosis is operated on as soon as possible. In cases of severe involvement in the cul-de-sac, total hysterectomy is much better than the subtotal operation. Drains do much harm than good.

T FLOYD BELL, M D

Doubtful Malignant Changes in the Endometrial Epithelium A Report on 60 Cases from the Radiumhemmet GILBERTO MARRUBINI *Acta radiol*, Stockh, 1948, 31 65

In this article 60 "debatable cases," which are markedly suspicious but not characteristic of malignant changes of the endometrium, are discussed from the clinical and the microscopic standpoints. These are borderline cases between the benign and the malignant, and comprise 54 per cent of the total series of cases of cancer of the uterine body observed by the author. The strong suspicion of malignancy, both from the pathologic and the clinical standpoints, was in every case an indication for the line of therapy adopted. Treatment with radium was given

in doses commonly used for uterine cancer, and followed up for at least 5 years

Ten per cent of the 60 cases reported here, in spite of the radical treatment given, showed the development of adenocarcinoma later, 5 cases in the endometrium and 1 case in the fallopian tube

For the histological examination the material has been divided into 3 groups, as follows

1 Cases in which there are suspicious changes in a functional endometrium

2 Cases showing a very marked glandular proliferation in a nonfunctioning endometrium

3 Cases in which the changes suspicious of malignancy are found in an endometrial polyp

In all the cases, changes occurred solely in glands and glandular epithelium. The glands were very frequently increased in number, sometimes enormously so, and more often so closely packed as to resemble the structure of a highly organized adenocarcinoma. Great differences were observed in their shape and size, cystic changes were noted in some of these cases, as well as irregular packing of convoluted glands. There were irregularities of the glandular epithelium. Abundant mitoses were often found and differences in staining were frequent, as well as other atypical features.

The most important general reasons why a definite diagnosis of adenocarcinoma could not be made were

1 The epithelial changes were always confined to the glands without any obvious destruction of the membrana propria

2 The different types of changes described did not all occur in the same case

The findings seemed to indicate that the suspicion aroused by these pseudomalignant lesions is graver in cases showing endometrial polyps or atypical glandular proliferations in a nonfunctioning endometrium than in cases with an endometrium of functioning type.

The occurrence of these pseudomalignant lesions in the postmenopausal period should be regarded with more suspicion than such occurrence during the menopause or before. This fact is substantiated by the finding that 5 of the 6 patients who developed a true carcinoma had passed the menopause.

The symptomatology was usually limited to irregular bleeding of varying duration. In the postmenopausal patients this symptom was far more suspicious of uterine neoplasm than in the patients in the menopausal period.

No definite conclusions can be drawn from this study as to whether these cases should be considered to have been truly malignant *ab initio*. Radical treatment in all cases seems justified. As these lesions appear to be confined to the endometrium, a radical effect following the treatment is to be expected.

Furthermore, since these changes are not unequivocally benign, and since careful radium therapy involves little risk, the author believes all patients with these changes should be given the benefit of this treatment.

T FLOYD BELL, M D

Unsuspected Cervical Cancer in Gynecological Patients HAROLD SPEERT *Am J Obst*, 1949, 57 947

Fourteen cases of unsuspected cervical carcinoma are reported which were discovered postoperatively by pathologic examination. Approximately 2 per cent of all cervical cancers were discovered in this manner. In 5 cases, total abdominal hysterectomy had been performed. In 8 instances, the tumor was found in tissue removed incidental to plastic operations. In 1 case, the tumor was revealed on postoperative biopsy after subtotal hysterectomy.

Meticulous examination of the cervix by means of biopsy of suspect areas should precede all major gynecological operations, while routine curettage is a worthwhile preliminary to vaginal plastic operations to exclude unsuspected endocervical and endometrial cancer.

GEORGE BLINICK, M D

Four New Cases of Malignant Neoplasm on the Cervical Stump (Quattro nuovi casi di neoplasia, maligna, sul moncone cervicale) FRANCO OLIVELLI *Ginecologia*, Tor, 1948, 14 584

The intervals between operation and the onset of clinical manifestations in 4 patients varied from 15 months to about 9 years. The carcinoma found after 15 months might be suspected of having been present at the time of operation, since some authors regard 2 years as the minimal free interval to exclude a pre-existing malignant tumor, but considering the variability in the speed of development of cancer and accepting, with Tagliaferro, the period of one year as a sufficient free interval, it must be admitted that no diagnostic error was made in this case. However, there is another question, i.e., whether at the time of hysterectomy there was any sign suggesting the possibility of later development of cancer in the cervical stump.

Case histories revealed the following conditions in the first patient, a marked familial tendency to carcinoma, in the third patient, a glandular endometritis, in the fourth, a hypertrophic portio with a small erosion in which diagnostic curettage disclosed an interstitial endometritis, and in the third and fourth patients, cervical lacerations.

The indications for hysterectomy had been fibromyoma of the uterine body in 1 patient, metroendometritis with hemorrhagic content in 2 patients, and bilateral ovarian cystoma with apparently intact uterus in 1 patient. This variability is in contrast with the observations of most authors who have found that in the majority of cases carcinoma appears in stumps of previous hysterectomies for fibromyoma, but it is evident that this finding is due to the fact that fibromyomas present the most frequent indication for subtotal hysterectomy.

Various theories have been advanced to explain malignant degeneration of the stump. In the opinion of some authors, elimination of ovarian function would be a factor predisposing to cancerization by atrophy occurring in the stump, or by loss of the influence of the ovary on the connective tissue defense

TABLE I — AN ANALYSIS OF RESULTS BY THE TWO MAJOR TYPES OF THERAPY

		Number of cases	Cured	Percentage
A Radiation treatment (344 of 396 or 86.9%)	Group I	79	61	77.2
	Group II	174	78	44.8
	Group III	77	17	22.1
	Group IV	14	0	0
	Group I-IV	344	156	45.3
B Operative treatment (38 of 396 or 9.6%)	Group I-II (Wertheim)	23	14	60.9
	Group I-II (Schauta)	12	6	50.0
		35	20	57.1
	Palliative hysterectomy	3	0	
C Untreated (14 of 396 or 3.5%)	Group IV	14	0	
	Total	396	176	44.4
A+B+C				

TABLE II — COMPARISON OF RESULTS OF TREATMENT FOR VARIOUS PERIODS

	Number of cases	Cured	Percent age	Relative cure rate	
				I/II in per cent	III/IV in per cent
1913-1928	623	149	23.9	41.3	10.6
1925-1930	339	101	29.7	40.4	13.9
1930-1936	329	121	36.8	49.0	—
1936-1942	396	176	44.4	55.2	15.7

Results of Treatment of Carcinoma of the Cervix Uteri in the Period from 1936 to 1941 (Be-handlungsergebnisse beim Carcinoma colli uteri, 1936-1941) H RUNGE and H WIMHOEFER *Geburtsh. & Frauenh.*, 1949, 9 84

The authors report on their results of therapy in 396 cases of cervical carcinoma observed from 1936 to 1941 at the Gynecological Clinic of the University of Heidelberg. Less than 10 per cent of the patients were treated by surgery and nearly all the remainder by combined x ray and radium irradiation. The absolute cure rate amounted to 44.4 per cent, and the relative cure rate for the operable cases was 55.2 per cent and that for the inoperable ones, 15.7 per cent.

Grouping of cases was determined clinically, as follows

- Group I Carcinoma limited to the cervix
- Group II Spread of the carcinoma to the vagina or slight invasion of one or both parametrial areas
- Group III Unilateral or bilateral parametrial spread directly to the bony pelvic wall
- Group IV Frozen pelvis, invasion of the bladder or rectum and distant metastases

The similar results in similar cases treated by radiation or surgery is to be noted. Clinical grouping and not histologic grading is important in determining the prognosis. Cervical carcinoma in women

under 50 years of age or accompanied by an inflammatory reaction during or following radiation therapy also points to a poor prognosis.

A comparison of the statistics for the period from 1936 through 1941 with those of a previous period is presented in Table II. There has been a marked improvement in the results through the years.

WARREN R. LANG, M D

Wertheim's Operation in Retrospect. VICTOR BONEY *Lancet*, Lond., 1949, 1 637

The author reviews the early history of Wertheim's operation and reports his own first successful operation in 1907. He departed somewhat from that of Wertheim. He removed routinely the regional glands and from one-half to the whole of the vagina. In 1941, Bonney reported the results of 500 operations on a 5-year basis, and of 415 operations on a 10-year basis. The 5-year cure rate was 40 per cent, or 43 per cent according to the method of calculation, and the operative death rate was 14 per cent. On the 10 year basis the cure rate was 31 per cent or 36 per cent, and the operative mortality slightly less than 14 per cent.

The cures in the group of cases without gland involvement were far greater in number than those in the cases with gland involvement. There was a greater

difference, too, in the respective operative mortalities, those of the first group amounting to 10 per cent and those of the second group, 20 per cent

Surgery can effect one 5-year cure in every 4 unselected patients, and one 10-year cure in every 5 unselected patients. In addition, there is another group from which patients can be salvaged by irradiation. The author believes that certain cases of cancer of the cervix are best treated by surgery, while others are best treated by irradiation. Among the cases which should be treated by surgery are those in which the growth is refractory to irradiation, and it is of the utmost importance that some method be found by which refractoriness or vulnerability can be distinguished before any treatment is decided on.

The author hopes for the day when a specific cure for cancer will be found. Till then, surgery and radiotherapy must be relied upon.

T FLOYD BELL, M D

ADNEXAL AND PERIUTERINE CONDITIONS

Limitation and Extension of the Syndrome of Demons-Meigs (Limitation et extension du syndrome de Demons-Meigs) P FUNCK-BRENTANO
Presse méd, 1949, 57 341

Now that the period of the reporting of curious syndromes has passed (which was the purpose of the reports of Demons a half century ago), and we are introduced to a well defined clinical entity, the syndrome described by the American, Meigs—because of its vital, practical importance therapeutically—needs to have its frontiers rigidly defined.

The conditions necessary for qualification of the disease as the syndrome of Demons-Meigs are the presence of a benign ovarian fibroma accompanied by a bilateral, or unilateral, hydrothorax and an ascites. However, the author believes that to these conditions as an entity should be added (under the term "syndrome of Demons-Meigs") the partial syndromes of ovarian tumor plus hydrothorax, and of ovarian tumor plus ascites. The manifestations should, of course, be immediately and definitively curable by ablation (castration) of the ovarian tumor.

In the Demons-Meigs syndrome, the hydrothorax may precede the ascites (this naturally disposes of the theory of transudation of the fluid exclusively and immediately from the tumor surface itself) or the ascites may precede the hydrothorax. Neither the fluid from the pleural cavity, nor that from the peritoneal cavity will contain blood or tumor cells. This will perhaps have differential diagnostic importance. Another characteristic of this condition which may have diagnostic significance is the vast predominance of the hydrothorax limited to the right side of the chest.

The author quotes extensively from the writings of Demons, in the years 1901 to 1903, to show that he was actually discussing the condition which has recently been erected into a syndrome by Meigs.

JOHN W BRENNAN, M D

Peritoneal Bodies and Cysts of the Broad Ligament

R. R. GREENE, B M PECKHAM, and G H GARDNER. *Am J Obst*, 1949, 57 890

This excellent article on peritoneal bodies and cysts of the broad ligament is timely and has as a background a tremendous amount of original research by the authors. They do not believe that men's names such as "Walthard" should be applied to anatomic or pathologic structures. They believe, and it is the modern trend in nomenclature, that terms should be descriptive, or of etiologic significance.

The material was derived from routine slides of one or both salpingo-oophorectomy specimens from 150 patients. In addition, the lateral half of the tube, broad ligament, and ovary from 16 patients were serially sectioned and studied. Routine sections were stained with hematoxylin and eosin, in addition, Milligan trichrome and iron hematoxylin with mucicarmine have been used.

The authors found these solid or cystic bodies in specimens from 78 patients. A total of 58 solid bodies and 78 of their cystic derivatives were found. These do not include the findings from two serially sectioned specimens. One surface of one broad ligament and both surfaces of the other were literally covered by these solid or cystic structures. In the routine tissues the number of solid bodies varied from 1 to 3 per specimen and the number of cystic structures from 1 to 12.

The solid bodies were a mass of epithelial cells with distinct cell membranes, faintly staining cytoplasm, and vesicular nuclei with little or no chromatin. There was infolding of the nuclear membrane resulting in bizarre nuclear shapes. There were no intercellular bridges, no basement membrane surrounded the body, and there was no true capsule.

The process of cavity formation and cystic dilatation could be observed in various specimens. In early cavity formation the adjacent epithelial cells were cuboidal or even columnar. This is thought to be a degenerative phenomenon. As fluid accumulated the number of cells in the wall became fewer until in the larger ones the epithelium consisted of usually two layers and, more rarely, a single layer.

The authors state that the impression is current that these structures are found only on or just below the serosa of the tube. A group of 67 solid or cystic bodies in which the position could be accurately determined was tabulated, 33 were on the tube and 34 on other areas of the broad ligament. Of the latter, 9 were on the mesovarium and 25 on the mesosalpinx. The authors note that most of their blocks were cut to include the tube, mesosalpinx, mesovarium, and at least part of the ovary. It was thus possible to survey the serosal surface of all the constituents of the broad ligament in a single section.

A few of the solid bodies showed direct continuity with the mesothelium, only a portion of the mass being subserosal. In other routine sections solid bodies and some showing a moderate degree of cystic dilatation were located immediately under but not

continuous with the mesothelium. Some that were serially sectioned showed continuity with the mesothelium and some did not and still others were not serially sectioned.

Gross pathology reports and microscopic specimens from 35 patients were examined particularly for evidence of present or past inflammatory reactions, which were found in 32 specimens. The evidence of active inflammatory reaction was quite obvious, it was usually a subacute perisalpingitis associated either with ectopic pregnancies or, more frequently, with endometriosis. Adhesions alone or in association with other old inflammatory residuals were found in others. These too were associated with residues of pelvic inflammatory disease or with endometriosis. In 3 cases no evidence was found but it is possible, of course, that it had been present and left no evidence.

The authors recently described the detailed histologic characteristics of cysts of the broad ligament derived from the mesonephric duct, mesonephric tubules, and aberrant paramesonephric epithelium (tubal or Muellerian). Cysts of mesonephric or paramesonephric origin have a true capsule whereas peritoneal cysts do not. The epithelium of cysts of mesonephric duct origin is single layered and cuboidal and has a basement membrane. That of mesonephric tubule origin is more columnar and is composed of two types of cells—lightly staining ciliated cells and darkly staining nonciliated cells. The epithelium of cysts of paramesonephric origin is identical to that of the oviduct or tube and is composed also of two types of cells, ciliated and secretory. The epithelium of the peritoneal cysts, on the other hand, is composed of flattened cells, usually two layers in thickness.

Four main theories have been proposed to explain the histogenesis of the so-called Walthard bodies.

Rossa (1898) proposed that these bodies come from accessory adrenal tissue and that the cysts result from atrophy of this tissue. This theory has been generally discarded.

Schickele (1902) proposed that they came from ovarian germinal epithelium which in some manner had been transferred to the site of origin. The authors think this theory too complicated.

Ralph Reis recently suggested that they might develop from misplaced entodermal cells of cloacal origin because of the close similarity of these structures to the cell balls of Limbeck and Brunn which are found under the vesical and ureteral mucosa. The authors think this theory unlikely and state that because two structures are morphologically similar does not prove they are of the same embryonic origin.

The fourth and commonly accepted theory was proposed by Werth in 1887. He showed that these bodies develop as proliferations of the peritoneal epithelium. Robery Meyer (1903) published a thorough and convincing study on the subject.

The authors' studies and findings followed closely those of Werth and Meyer. Various stages in devel-

opment have been noted from the early localized areas of proliferation of the mesothelium—the down-growth of epithelial masses, the subserosal masses of epithelial cells no longer connected to the mesothelium, early cystic degeneration, and the final result, peritoneal cysts. BYFORD F. HECKETT, M.D.

EXTERNAL GENITALIA

Two Cases of Benign Connective Tissue Tumor of the Female External Genitalia (Due casi di tumore connettivale benigno dei genitali esterni femminili) CESARINA MUSANTE *Ginecologia*, Tor, 1948, 14 574

The first patient presented, on the free border of the left major labium between the anterior and middle thirds, a pedunculated tumor (the size of a nut) which was painless and had the characteristics of a fibroma or fibrolipoma. It had first been noted as a small nodule 3 years previously and had slowly increased in size. It was removed under local anesthesia, and histologic examination showed it to be a pure fibroma.

The second patient presented, on the edge of the prepuce of the clitoris, to the right of the median line, a neurofibroma which was round, pedunculated, and the size of a pea. It was excised, and histologic examination confirmed the diagnosis.

Tumors of the female external genitalia are infrequent compared to those of the internal genitalia, and benign tumors of the vulva are less frequent than malignant tumors. Benign tumors of epithelial nature are rare while benign connective tissue tumors are relatively more common. Usually they occur in adults, principally in the third decade. The order of frequency of their occurrence is as follows: fibroma, fibrolipoma, lipoma, myxoma, and angioma. Myomas, fibromyomas, neurofibromas, ganglioneuromas, enchondromas, and osteomas are rarer. The prevailing site of these tumors is the major labium, although they may involve (in order of frequency) the minor labium, the clitoris, and posterior vulvar commissure. Their volume may vary from that of a small nut to that of a large orange. Large tumors become pedunculated and may assume the aspect of the head of a polyp. Growth is slow and the tumors come under observation several years after their onset, largely because they cause no particular disturbance. They generally show a periodic increase in size during menstruation and pregnancy. Voluminous tumors impede ambulation, and sometimes also micturition, abrasion and circulatory disturbances of the pedicle may result in edema, ulceration, and discharge. With the exception of neurofibromas, they are painless, they are mobile on the underlying tissues, but may have connections with the formations of the inguinal ring. Their consistency may be soft, cystic, elastic, or fibrous. Calcification, rapid increase in volume from trauma, hematoma and, more often, malignant degeneration have been reported. According to Leonard, sarcomatous degeneration occurs in 22 per cent of vulvar fibromas.

Treatment is surgical, there have been recurrences of leiomyoma. The diagnosis in most cases presents no difficulties. In tumors of the anterior portion of the major labium, inguinolabial hernia, cyst of Nuck's canal, and neof ormation originating in the terminal part of the round ligament must be taken into consideration. In tumors of the posterior portion of the major labium, neoplasm of the gland of Bartolini must be excluded. In many cases the benign tumors originate from the connective tissue formations of the region. RICHARD KEMEL, M D

Carcinoma of the Vulva ARTHUR B LUNIN *Am J Obst*, 1949, 57 742

Carcinoma of the vulva occurs most often in elderly women but may also be seen in younger age groups. Forty-two per cent of the 50 cases in this series occurred in patients under the age of 50, the average age being 53 years. In 2 patients the disease of the vulva was complicated by pregnancy. In the New Orleans area the disease is as common in colored women as it is in white women. Fifty-eight per cent of the colored women had granulomatous venereal lesions of the vulva.

All lesions of the vulva that fail to respond to treatment in a reasonable period of time should be subjected to biopsy, and it is to be emphasized that one negative result does not rule out malignancy.

Treatment is surgical and should consist of complete vulvectomy with bilateral lymph node resection. Radiation has some value in palliation but will seldom effect a cure.

In a group of 22 patients treated prior to 1942 by a variety of methods, 4 (18.1%) were living without evidence of disease 5 years later.

JOHN R WOLFF, M D

MISCELLANEOUS

Vascular Congestion and Hyperemia The Clinical Aspects of the Congestion-Fibrosis Syndrome HOWARD C TAYLOR, JR *Am J Obst*, 1949, 57 637

A series of 105 patients were interviewed, examined, and followed up by the author in order to outline the clinical characteristics of the congestion-fibrosis syndrome. The findings were gradually accumulated during the last decade and represent the more severe and clearly defined cases of this disorder.

This concept of pelvic disease suggests that congestion as it is seen in the breast, ovaries, uterus, and parametria is a similar condition and that it tends to occur simultaneously in the same patient in more than one of these sites. The cases reported here are all examples primarily of pelvic congestion. All but one of these patients were in the years of ovarian function. The majority were married. Sterility and infertility were common.

The essential symptoms included increased menstrual discomfort with pain (usually premenstrual in type), a change in the character of the menstrual pattern, intermenstrual spotting, lower abdominal

pain, backache, and painful intercourse. Associated symptoms of tension and other psychosomatic disorders were common to this group of patients.

Parametrial fibrosis with thickness of the uterosacral ligaments was the most important finding in this condition. The uterus was usually enlarged, tender, and often retrodisplaced. Some degree of endocervicitis was usually present. The ovaries were always tender and somewhat cystic.

Patients with these symptoms and local findings in the reproductive organs and with general signs of autonomic instability present a consistent and characteristic clinical picture which seems properly termed, at least provisionally, the "congestion-fibrosis syndrome." JOHN R WOLFF, M D

Vascular Congestion and Hyperemia Etiology and Therapy HOWARD C TAYLOR, JR *Am J Obst*, 1949, 57 654

Pelvic congestion is a disorder of the pelvic circulation due to multiple causes, several of which may have to be present in a single patient to produce symptom-giving conditions. Predisposing constitutional factors are probably present in the autonomic nervous system and perhaps in the blood vessel structure of the susceptible patient. The tendency toward congestion is increased by loss of support of the pelvic structures after parturition, by malposition of the uterus, possibly by damage to the veins from postpartum phlebitis, and by occupations requiring the erect position and leading to excessive fatigue. The estrogens maintain the pelvic tissues in a state receptive to these stimuli and their physiologic premenstrual rise places most of the complaints in that part of the cycle, however, this disease is not due to any primary ovarian or other endocrine disorder. The autonomic nervous system is responsible for both acute and chronic vasodilatation as a result of unphysiologic sexual behavior as well as nonspecific emotional states.

The various aspects of chronic pelvic congestion have been and remain notoriously resistant to treatment. The development of a rational plan of therapy depends upon the understanding of the underlying physiologic disorder and the multiple factors which contribute to it.

Just as there is no single etiologic factor, there is no single method of treatment for the clinical syndrome based on congestion of the female reproductive tract. A plan of therapy for the individual patient must be built up from a careful evaluation of two aspects, namely, (a) the principal causative agent, and (b) the severity or the duration of the condition.

These disorders of the circulation and of the autonomic nervous system in the reproductive organs appear to be the basis of a considerable portion of all minor gynecological conditions and include many conditions now commonly classed as endocrine or inflammatory. Within this field are mastodynia, premenstrual breast engorgement and certain types of chronic mastitis, uterine congestion and hyper

trophy, many cases of menorrhagia and cervical hypertrophy, the majority of cases of "endocervicitis," congested and "cystic" ovary, and many of the cases of dyspareunia, dysmenorrhea, and obscure pelvic pain

The revaluation of gynecologic conditions to include this concept would constitute a major and, the writer believes, an essential revolution in gynecologic thinking

JOHN R. WOLFF, M.D.

Histophysiology of the Sexual Zone of the Adrenal Cortex (Histophysiologie de la zone sexuelle de l'écorce surrénale) JOSÉ BOTELLA LLUSIA *C rend Soc fr gyn*, 1949, 19 17

The close relationship between the adrenal cortex and the secretion of sexual hormones is a well established fact. Two different androgenic hormones as well as estrogen and progesterone have been isolated from the cortex of normal human beings and of different animals (cattle, pigs, horses). The presence of these hormones in the cortex is not surprising in view of the chemical similarity between the adrenal steroids and the sexual hormones.

Various investigators have attempted to establish a relationship between the secretion of sex hormones and certain histological layers of the cortex. Deanesley and Howard, in studies on the white mouse, described the "zone X," or "transitory zone," between the cortex and the medulla which seems to be derived from the reticular layer of the cortex. It develops during the embryonal stage and reaches its climax at the time of birth. After birth it atrophies but reappears when the animal is castrated. If the castrated animal is treated with testosterone, the tissue disappears again.

Under the name of "androgenic zone" Grollman described a layer between the cortex and medulla which reaches its greatest development in the human embryo of 3 or 4 months, especially in males, and disappears completely after birth. He believes that pathologic proliferation of rests of this zone causes adrenal virilism and, in females, pseudohermaphroditism.

Vines found characteristic fuchsinophil cells in 33 of 34 patients who had been operated upon for adrenogenic virilism. These cells were present in cases of simple hyperplasia as well as in adenoma or carcinoma of the cortex.

These physiologic and histologic researches of different writers have led to a certain confusion. In the first place, it is not clear whether the zone X, the androgenic zone, and the fuchsinophil tissue are identical or of different origin and significance. Furthermore, it is not certain if these tissues have relations to the secretion of androgenic hormones only, or to the formation of estrogen and progesterone as well.

In order to bring these questions nearer to a solution, the author studied the histology of the adrenal gland in human embryos (28 cases) as well as in adults (20 cases), 2 of whom suffered from adrenogenic virilism. Furthermore, in animal experiments

on rats and mice, he followed the development of the zone X during embryonal life and after castration, and the action of sexual hormones on involution. He arrived at the following conclusions:

Sexual hormones are secreted by a tissue of interstitial type situated between the cortex and the medulla. The "androgenic zone" (Grollman), the "zone X" in mice (Deanesley), and the fuchsinophil cells (Vines) are identical. This tissue is found in embryos of both sexes, although it is more developed in male embryos. The injection of sexual hormones causes the disappearance of the zone X as well as of the fuchsinophil inclusions.

This tissue is a physiological entity which appears in different forms, according to the species and the period of life. It represents a sort of "third gonad" with its main activity before and after the period of testicular or ovarian activity. Since it is found in both sexes, the author suggests calling it the "sexual cortical zone" rather than the androgenic zone.

WERNER M. SOLMITZ, M.D.

The Ureter, the Gynecologist, and the Urologist
President's Address. TERENCE MILLIN *Proc R Soc M*, LOND, 1949, 42 37

Lesions and injuries of the ureter which are of interest to the gynecologist are discussed in detail. The more frequent use of intravenous urograms, both preoperatively and postoperatively, will yield much useful information.

Congenital abnormalities of the ureter may produce diagnostic difficulties, such as supernumerary or ectopic ureters opening into the urethra or vagina and causing persistent incontinence. The supernumerary ureter and the congenital megaloureter are prone to injury at abdominal operation if unrecognized.

Operative accidents to the ureter may be recognized at the time of operation. If the ureter is cut high up, the correct procedure is immediate anastomosis over an indwelling ureteral catheter. The suture line is extraperitonealized and a drain is placed appropriately. If the ureter is sectioned low in the pelvis, it may be preferable to reimplant the ureter into the bladder. Ligation of the proximal end of the cut ureter can very rarely be justified today. If the ureter has been caught in a clamp and the injury is minimal, it will probably only be necessary to place an extraperitoneal drain. If the clamping has been complete, it will be best to excise the crushed area and perform an end-to-end anastomosis.

A second group of operative accidents to the ureter are not recognized until later when renal pain, infective phenomena, or fistula make the diagnosis plain. A small proportion of ureterovaginal fistulas heal spontaneously. However, at present the author advises early operation, i.e., before stenosis, leading to upper urinary tract dilatation and infection, has occurred. The extraperitoneal approach is preferred and since the damage to the ureter is usually low down, the best procedure in most cases will be a reimplantation into the bladder. Ureteroureteral or ureterocolic

anastomosis may be performed. When there is doubt as to whether reparative surgery or nephrectomy is indicated, a modified Gibson incision is employed.

Dilatation of the ureters is found in pregnancy, in pelvic inflammations and tumors, in genital prolapse, and in carcinoma of the cervix. In the latter, it may be the result of malignant compression, but not infrequently it results from postirradiation fibrosis. Investigation of the genitourinary tract and appropriate therapy will lead to improved results.

Postoperative anuria is a serious complication. Certain varieties are well known, chiefly those following excessive therapy with sulfonamides. Lesser known varieties are even more important. One has to determine whether the cessation of urinary output is prerenal or postrenal. If doubt exists, a prompt recourse to surgery will often be warranted. A rapid examination of the upper ureter will be the key to the problem. If it is dilated, then we are dealing with a postrenal obstructive phenomenon, if it is not dilated, then we have a prerenal lesion to contend with. In the former, a ureterostomy, or a nephrostomy will relieve the obstruction and be lifesaving, in the latter, a prompt decapsulation is most likely to yield satisfactory dividends although beneficial results have, on occasion, followed splanchnic block and spinal analgesia.

GEORGE BLINICK, M.D.

Urethral Diverticulum in the Female. A Clinical Study. VIRGIL S. COUNSELLER. *Am J Obst*, 1949, 57: 231.

Diverticula of the female urethra are not common, nor are they actually uncommon. The symptoms appear bizarre and yet they are diagnostic when carefully studied. It seemed to the author, with these facts in mind, that the findings in 71 cases of diverticulum of the female urethra in which surgical treatment was employed at the Mayo Clinic, and the impressions formed from study of these cases would be of interest. A much larger group of patients who had small sacculations, deformities, and postoperative irregularities or scars which responded to local treatment and dilatations of the urethra were studied, but data on these patients are not included in this report.

The average age of the 71 patients was 41 years. Thirty patients were from 31 to 40 years of age, 27 from 41 to 50 years of age, 6 were 30 years of age or less, and 8 were more than 50 years of age. None of the patients were children.

The duration of symptoms is important. Symptoms may exist for only a few weeks and can last for 33 years or more, as in one of the author's cases. Most of the patients in his group had symptoms for more than 5 years, the usual period was from 5 to 10 years. The cardinal symptoms were pain and frequency of urination, leakage of urine, dyspareunia, and, finally, a vaginal mass.

The urinary symptoms may range from mild to severe. Often the urethra does not show any local inflammation at all but the voided specimen will contain large amounts of pus even though contami-

nation from the vagina is excluded. The catheterized urine may be entirely negative and this fact may lead to a mistaken diagnosis. On account of the symptoms of urethritis, and without much evidence of anything else, the urethritis of most of the 71 patients in the author's group had been excessively treated with local applications and with heat and tampons.

Pain is a significant symptom and its presence should make the physician at least suspect the presence of a diverticulum of the urethra. It is of 4 types: (1) low abdominal or suprapubic, like that usually produced by cystitis, (2) perineal, which appears to extend down through the perineal region and rectum, (3) vaginal, which usually consists of a sense of pressure or weight in the vagina, and (4) pain which frequently darts upward from the urethra and through the vagina to the pelvic organs. Pain in the sites and of the types described occurred in 55 per cent of the 71 cases.

Leakage of urine or a discharge from the urethra was noted in 40 per cent of the cases.

Dyspareunia was experienced by 10 per cent of the patients and was a complaint of those who had rather acute inflammatory reactions in the anterior vaginal wall.

A mass in the anterior vaginal wall was noted by 40 per cent of the patients.

The severity of the complaint is also significant. It is out of all proportion to that which the physical findings concerning the urethra indicate should actually be produced. There is no relation between the complaint and menstruation.

Vaginal examination with careful palpation of the anterior vaginal wall under the entire urethral region may reveal some induration or a definite mass. Pressure on the mass will cause foul smelling urine or pus to exude from the external urethral orifice unless the orifice of the diverticulum has been occluded by the inflammatory process. If there is only induration, the diverticulum can be more easily identified if a urethroscope is placed in the urethra and then the urethra is palpated over it.

Cystoscopy is not always successful in identifying the diverticulum. Sometimes the orifice is not easily seen.

Any local treatment, such as massage, dilatation, or instillations, is of no value when a true diverticulum exists. Transurethral incision of very small diverticula for more adequate drainage may be useful. The best treatment, however, is complete surgical excision of the diverticulum and repair of the urethra. This can be accomplished in practically all cases except the few in which abscesses are present. In these few instances, the orifice of the diverticulum may be necrotic and cannot be closed by suturing. A urethral fistula then would result and this fistula should be repaired only after all evidence of inflammation has subsided. When the inner wall of the diverticulum extends posteriorly along the urethra, it usually is intimately attached to the urethra and no attempt should be made to separate the wall of

the diverticulum from the urethra. To do so may cause multiple fistulas.

Surgical excision may be difficult unless the diverticulum can be seen readily. A retention catheter, between Nos. 18 and 22, should be placed in the bladder as a preliminary procedure, so that the identity of the lumen of the urethra is always known. The anterior vaginal wall should be mobilized, preferably between two small clamps or hemostats, and should be opened from just behind the external urethral meatus to the area of the trigone of the bladder. The fascia over the urethra is incised and separated from it and the vaginal wall, as in the repair of urethrocele. As the surgeon cuts with a sharp scalpel directly down on the urethra, the diverticulum as a rule begins to bulge into view. With the catheter in place in the urethra, the diverticulum can be distinguished from the urethra. At this point the diverticulum can be grasped with a clamp and further separated from the surrounding tissues.

When the diverticulum is definitely identified, it should be opened and its contents, if any, evacuated. The extent and direction of the sac can be accurately determined by examination of the interior of the sac under direct vision. The relation of the inner wall to the urethra can be observed. If the diverticulum is firmly adherent to the urethra and at all inflammatory, all of the sac should be excised except that small segment along the urethra. The orifice in the urethra can be closed with interrupted fine catgut sutures. This region should be reinforced by a running suture which closes the fascia over the entire urethra including the defect. A catheter is maintained in the urethra for only 4 to 5 days, the patient then is advised to go to the bathroom and void. Subsequent catheterizations are inadvisable.

Urethrovaginal fistulas which occur subsequent to repair of cystocele, urethrocele, or vaginal hysterectomy could easily be due to a urethral diverticulum which was overlooked previously.

The Operative Treatment of Female "Stress" Incontinence HERMAN WAHREN *Acta chir scand*, 1949, 97: 331

Stress incontinence is believed to be due to a change in the position of the neck of the bladder relative to the symphysis and to changes in the musculature surrounding the bladder, particularly the levator ani, rather than to insufficiency in the sphincter musculature. Therefore, the surgical cure should be directed toward restoring and supporting the position of the fundus and the neck of the bladder. This is best accomplished by the transposition (interposition) operation.

In cases in which the transposition operation is contraindicated, the author has grafted bone chips between the cervix uteri and the wall of the bladder in 7 cases with satisfactory results, according to the following technique.

The portio is drawn down. A small transverse incision is made in the anterior fornix, and the posterior wall of the bladder is laid free from the cervix uteri so that a piriform space is shaped behind the neck of the bladder, 5 to 7 c.c. bone chips are inserted in this space. The bone tissue can conveniently be taken through a small osteotomy on the medial side of the upper part of the tibia. The material should, for the greater part, consist of cancellous bone which combines better in healing with the soft parts than the cortical chips. The material can easily be excised with a spoon.

GEORGE BLINICK, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Ectopic Pregnancy with Special Reference to Abdominal Pregnancy JULIUS JARCHO *1m J Surg* 1949 77 273, 473

This article is based upon a comprehensive review of the literature and a detailed analysis of 173 cases of ectopic pregnancy (6 abdominal) representing an incidence of 1 in 60 obstetrical admissions, 1 in 44 gynecological admissions, or 1 in 113 combined admissions.

The etiological factors were not always evident, but 52.7 per cent of the patients had an old salpingitis, 20.8 per cent had infertility, and 19.6 per cent had undergone previous pelvic or abdominal operations. The diagnosis was correct in 92 per cent of cases, and was made on the basis of the history, and physical and laboratory findings. The greatest diagnostic problem was the atypical case in which most errors were made. The signs and symptoms most frequently encountered were amenorrhea (73%), abdominal pain (88%), vaginal staining or bleeding (73%), abdominal tenderness or rigidity (48%), faintness and weakness (47%), nausea and vomiting (32%), and tenderness on motion of the cervix (29.5%).

The leukocyte count ranged from 5,000 to 10,000 in intact tubes or in tubes with slow leakage, was about 15,000 in moderate recent hemorrhage, and from 15,000 to 30,000 with massive recent hemorrhage. The sedimentation rate varied from 5 to 30 minutes.

Other aids in diagnosis are cul-de sac puncture and colpotomy. Curettage, peritoneoscopy, and hysterosalpingography have little value.

Treatment consists of prompt laparotomy with complete removal of the tube for tubal pregnancy, cornual resection or hysterectomy for interstitial pregnancy, and ovariectomy for ovarian pregnancy.

Advanced abdominal gestation presents complicated problems in therapy, but in general no attempt is made to remove the placenta and the wound is closed without drainage.

Blood, plasma, and other intravenous fluids are of utmost importance in keeping the mortality low. In this group of patients it was 2.9 per cent. Among the 9 patients with abdominal pregnancies there was one death. J. ROBERT WILLSON, M.D.

Cervical Pregnancy DANIEL G. MORTON *1m J Obst.*, 1949, 57 910

Cervical pregnancy is a comparatively rare type of ectopic gestation which is of special interest because of its uncertain etiology, the difficulties in making a correct diagnosis, and the high mortality of 20 per cent. The author presents a report of one "probable" case and one proved case of cervical pregnancy.

The first patient was admitted after several weeks of staining, with a mass of placental tissue lying in the cervical canal. An attempt to remove the placental tissue resulted in profuse bleeding and digital palpation of the interior of the cervix revealed a cavity 3 cm in diameter. With repeated picking of the endocervix and transfusions, she recovered. Subsequently, she became pregnant again and delivered spontaneously at term without difficulty.

The second patient was approximately 3½ months pregnant when she experienced vaginal bleeding and abdominal cramps. On her second hospital admission the products of conception appeared to protrude from the external os. A macerated fetus was removed and severe bleeding necessitated vaginal packing and transfusion. On two successive days attempts at removing the placenta produced profound shock from excessive hemorrhage. A laparotomy was performed, at which time the diagnosis of cervical pregnancy was made. Because of technical difficulties it was necessary to amputate the uterus at an undetermined point in the cervix as low as could be reached. Numerous transfusions were required postoperatively and there was continued vaginal bleeding. On the thirty-sixth postoperative day, a second laparotomy was performed and because of the inflammatory induration about the cervix it was deemed advisable to evacuate the cervix and close it without further operative procedure. She was discharged 14 days later, having received 11,000 cc of blood. The pathological report was cervical pregnancy with partial separation.

Cervical pregnancy is usually confused with abortion. However, the products of conception are not readily expelled from the cervix since the force of uterine contractions is absent. Thus undue delay in the completion of abortion may be of diagnostic value, particularly if a small uterine fundus can be palpated above the ballooned-out cervix. Forceful removal of the placenta usually results in copious hemorrhage since there is no muscular mechanism in the cervix designed to clamp off the subplacental blood sinuses at separation of the placenta, as there is in the corpus.

Every effort should be made to diagnose the condition before any manipulation is undertaken. Separation of the placenta should be avoided, and indeed the placenta might profitably be tightly packed against the cervical wall, particularly if there has been a partial separation. Thrombosis of vessels and gradual absorption should occur in the same manner as they do with a placenta left in the peritoneal cavity after an abdominal pregnancy. Finally, at removal, preparations for immediate transfusion and repacking should be at hand, since exsanguination may occur in a very short period of time. It is possible that in time the placental tissues would be absorbed completely. GEORGE BIRNIE, M.D.

A Variant of the Hofstaetter-Cullen Sign in Intra-Abdominal Hemorrhage from Ectopic Pregnancy JOHN FALLON and JOHN J. MANNING *N England J M*, 1949, 240 747

The Hofstaetter-Cullen sign need not be blue, can appear elsewhere than at the umbilicus, and is far from pathognomonic of extrauterine pregnancy. Probably, it can be caused by any condition producing colored intra-abdominal fluid.

A variant of the sign is reported, it consists of symmetrical, red, circular stains at either side of the umbilicus, over points where vessels often perforate the rectus sheath.

The location of the stains in the author's case and in 2 somewhat similar cases, as well as the more ordinary localizations over hernias, in scars, and at the umbilicus, suggests that the pigments that usually produce the phenomenon may reach their destination by following ordinary fascial planes and openings rather than by depending upon exceptional lymphatic function or subvisible peritoneal apertures.

CHARLES BARON, M D

Capillary Fragility and the Use of Rutin in Toxemias of Pregnancy W J DIECKMANN, Z AKBASLI, and G T ARAGON *Am J Obst*, 1949, 57 711

The capillary fragility was found to be increased in 33 per cent of the patients who had essential hypertension during pregnancy. The duration or severity of the hypertension seemed to be of no significance. Pregnancy seemed to accentuate the capillary fragility, possibly because of an associated, relative, or absolute anemia.

Capillary fragility was not increased in patients with either mild or severe pre-eclampsia, nor was it associated with abruptio placentae.

Rutin was used in 13 patients, in 12 of whom it was found efficacious in reducing the increased capillary fragility.

JOHN R. WOLFF, M D

Certain Aspects of Eclampsia H. J. STANDER and R. W. BONSNES *Am J Obst*, 1949, 57 482

The etiology of eclampsia is unknown, although the number of theories (past and present) proposed to explain its causation is legion. The authors state that many of the theories postulated in the past have, at present, only an historical interest, yet we are still left with a long list of theories. They discuss several of the modern beliefs and consider that what we need is more data, especially data to explain the consistently observed phenomena which occur during eclampsia.

Studies on nonprotein nitrogen, urea nitrogen, uric acid, CO_2 combining power, urea clearance, and blood chloride determinations in eclamptic patients are presented. The method of delivery, maternal and fetal mortality, and the subsequent course in 76 cases of eclampsia are summarized.

A plea is made for the study of more factual data in eclamptic patients. The etiology of eclampsia, although unknown at present, should be discoverable

by the application of the scientific method. A theory of eclampsia should be, then, a working hypothesis to be tested by experiment.

JOHN R. WOLFF, M D

Anemia of Pregnancy Treated with Molybdenum-Iron Complex WILLIAM J. DIECKMANN, HAROLD D. PRIDDLE, ROSE TURNER, and BETTY TREPTOW *Am J Obst*, 1949, 57 541

In 1936 a survey of pregnant patients at the Lying-In Hospital, Chicago, showed that 11.5 per cent of the patients were anemic, according to the standards for normal pregnant women. In 1947, using similar methods and standards only, 4.6 per cent were found to be anemic.

The 1936 survey showed that iron salts were of little value in the treatment of anemia of pregnancy.

The present study was made for the purpose of determining the value of a molybdenum-iron complex in the treatment of these anemias. There were 39 patients in the control group and 49 in the group receiving treatment. Forty-five of the patients who received treatment gained an average of 2.11 gm hemoglobin before delivery (minimum, 0.6 gm, maximum, 5.5 gm).

In determining the question of anemia, it is believed that a hematocrit determination performed every 3 months, one at or near term, and one also at 6 weeks postpartum is the most accurate.

A hemoglobin which is less than 12 gm (hematocrit, 37 per cent) in the first 12 weeks, or which is not at this level 6 weeks postpartum is indicative of anemia. From the twelfth to the thirty-sixth week the lower limit of the hemoglobin in pregnancy is 10 gm (hematocrit, 30 per cent). The lower limit from 36 weeks to term is 10.5 gm (hematocrit, 32 per cent).

A molybdenum-iron complex has been found to be very effective in causing significant increases in the hemoglobin concentration of most patients within a 3 week period. If the hemoglobin does not show a significant increase in this period of time, further hematologic studies are indicated.

JOHN R. WOLFF, M D

Operation for Severe Varicose Veins during Pregnancy HAROLD DODD *Lancet*, Lond, 1949, 1 606

Numerous reports from the literature are cited in which successful and good results were obtained by ligation, injection, or both, of severe varicosities in pregnant women. Other opinions have been to the effect that any treatment of this type during pregnancy is contraindicated.

Dodd reports 17 cases treated by him in which the patients showed good improvement. There were no complications in either mother or child, and all of the babies were born uneventfully. The operations were done between the second and the seventh months of pregnancy.

The author tests the patency of the deep system of veins by tourniquet and differentiates seven different types of varicose veins. The operation can

plete dilatation, (2) at the transition from the first to the second stage of labor, or the "pain period of labor," which is referred to the lumbosacral region as backache, (3) when the advancing head meets the pelvic floor (the reaction is one of escapism, and leads to complaints of utter exhaustion or frustration), and (4) at the time of early crowning of the head when there is a feeling of an inevitable splitting of something, sometimes accompanied by an acute stinging or burning pain.

The author believes that the patients should be comforted at these various menaces and offered encouragement or relief if they want it. He states that few ask for relief and some resent the suggestion.

The co-operation of the patient in labor depended on antenatal preparation: (1) the education in, and understanding of, the process of pregnancy and labor, (2) the ability to relax during the first-stage contractions and between the second-stage contractions, (3) physical preparation by a few simple exercises designed to give full, free, and controlled respiratory movements, mobility of the pelvic joints, and general muscular fitness. The unrestrained happiness of the good co-operator at birth of her child is not only a delight to witness but also has an important physiological and emotional significance. In many cases the husband and wife took tea together within 10 minutes after the expulsion of the placenta, mutually happy with the newborn beside them. There was no evidence of infection of the babies by the attentions of their parents.

All babies except 9 were breast-fed. The author believes the so-called "slow starters" should not be given complementary feedings because the milk often increases when the mother gets home to her natural environment.

Among the 52 cases in which forceps deliveries were done, 26 of the patients had emotional breakdowns. However, 13 expressed disappointment at the interference and 4 wept when they were told that they would not see the baby born. Twenty-two had an occiput-anterior presentation with no disproportion, 5 had an occiput-anterior presentation with some relative disproportion, 7 had transverse arrest at the midcavity, and 18 had persistent occiput-posterior presentations. In 3 cases the operation was done for fetal distress. Of 6 women who were ill and who underwent forceps deliveries 1 had been ill with pycelonephrosis for 3 months, 2 had toxemias of pregnancy, and 3 were mentally unstable and had been treated in mental homes.

The author states that ordinarily an incidence of 5.4 per cent for cesarean section would demand explanation. He believes there was a high incidence of borderline cases, and women who had experienced difficulty or had had cesarean section came under his care. Of 18 primiparas all had been classified as "small," either clinically or roentgenologically. A generally contracted or deformed pelvis was found in 6 and section was done, 2 women had forceps delivery and 10 had physiological labor. The 13 multiparas had had cesarean section for their first

and only child. Of these, 7 had a febrile puerperium and untrustworthy scars and a second section was done, 1 had a deformed pelvis and section was done, 4 had easy physiological labors, and 1 had a low forceps delivery. One small woman, having had 2 sections, was allowed a natural labor. Two elderly primiparas obsessed with the horror of labor were sectioned to avoid the risk of a serious breakdown. Diabetes mellitus, toxemia, and antepartum hemorrhage were the indications for 7 cases of section.

BYFORD F. HESKETT, M.D.

Five Thousand Consecutive Deliveries Without Maternal Death. NORMAN EMBLIN. *Brit. M. J.*, 1949, 1: 260

In the Halifax Municipal Obstetric Service, during the period between September 12, 1946 and October 5, 1948, there were 5,000 consecutive deliveries after the twenty-eighth week without a maternal death due to pregnancy. This number includes all women after the twenty-eighth week of pregnancy (a) who were admitted to the Halifax General Hospital from inside or outside the borough, whether to the general medical and surgical wards, the maternity department, or the special unit for the reception of septic cases, and (b) who were delivered in their own homes by the Halifax Domiciliary Service or independent midwives. No emergency case has ever been refused admission. In this series there was one death from acute myeloblastic leucemia and therefore not attributable to pregnancy.

The rate of forceps deliveries was 4.16 per cent and that of cesarean section, 1.06 per cent. There were 4 cases of eclampsia, 3 of these in unbooked cases. The stillbirth rate was 23.07 per cent and the neonatal death rate, 11.91 per cent. A brief summary of the treatment of some major complications is given. The belief is expressed that the most important single factor in reducing maternal mortality is the provision of a skilled staff to deal with abnormalities.

GEORGE BLINICK, M.D.

Extraperitoneal Cesarean Section in the Profoundly Infected Patient. MILTON L. MCCALL. *Am. J. Obst.*, 1949, 57: 520

The author presents a survey of the value of extraperitoneal cesarean section in the profoundly infected patient. Eighteen such cases are reported in detail. All patients were in prolonged labor with the membranes ruptured. The cases showed evidence of either neglect or exceedingly bad management. Unsterile vaginal examinations, attempts at manual cervical dilatation, or unsuccessful instrumental delivery had been done. High fever, tachycardia, and signs of dehydration and sepsis were present in each instance.

Since 38 per cent of all deaths following cesarean section are due to peritonitis, and since many or all of the contraindications for transperitoneal cesarean section (either classical or low cervical) were exceeded, this procedure was not to be considered in any of these patients. Many of the patients had

INTERNATIONAL ABSTRACTS OF SURGERY

already received antibiotics and sulfonamides without value
 Cesarean hysterectomy, embryotomy, and extraperitoneal cesarean section were the available methods

The management of these cases prior to the time of the extraperitoneal operation is not condoned by the author. Unfortunately, such instances still develop and their solution previously has been a fearful one.

All of these severely infected patients were treated by means of the modern extraperitoneal cesarean section. There was no maternal mortality.

Ninety-one consecutive cases of extraperitoneal cesarean section are reported without a maternal mortality. In 64 patients, contraindications to transperitoneal cesarean section were present. The fetal mortality was 8.8 per cent, 9.4 per cent of the patients with infection had babies who died of infection or as the result of prolonged labor.

The fact that women with the foulest of infections may be delivered safely by this method, all the while preserving the child-bearing organ, truly marks the newer technique of extraperitoneal cesarean section as a significant advance in modern obstetrics which should be recognized by all obstetricians until some simpler method, not yet known, appears to take its place.

Vaginal Delivery Following Cesarean Section
 HERBERT E. SCHMITZ and GEORGE R. BABA, *Am J Obst*, 1949, 57: 669

Should a patient with a history of cesarean section be subjected to an attempt at vaginal delivery?

During 18 years, 51 (32.4 per cent) of 157 patients with a history of cesarean section were successfully delivered via the vaginal route at the Lewis Memorial Maternity Hospital, Chicago, Illinois. Three instances of ruptured uteri occurred, but not in the patients subjected to a trial of labor. In these 3 cases, the rupture occurred close to term. In 2 cases the fetus was saved, and there was no maternal mortality or morbidity.

Vaginal delivery may be permitted under certain conditions when the management is under an experienced obstetrician at a hospital equipped to meet all emergencies. These conditions are (1) early engagement of the presenting parts, (2) a history of vaginal delivery preceding the section, (3) the diagnosis of a fetal death or a monstrosity in utero, and (4) reasonable assurance of a well healed scar (when the surgical technique is known to be good and the postoperative course is uneventful and afebrile). This, plus the absence of the original indication for section, will indicate a trial of labor.

In these 86 vaginal deliveries following 51 cesarean sections, labor and the puerperium were uneventful. There were 3 fetal deaths, an intrauterine death before labor, death of an 8 weeks old premature infant with hydrops fetalis, and death of a 10 weeks old premature 3 pound infant. The dictum "Once

a cesarean section always a cesarean section" should be changed to "Once a cesarean section, not necessarily always a cesarean section."

JOHN R. WOLFF, M.D.

PUERPERIUM AND ITS COMPLICATIONS

A Report on 159 Third-Degree Lacerations
 HAROLD A. INGRAHAM, MILTON M. GARDNER, and GEORGE HEUS, *1st J Obst*, 1949, 57: 730

There were 159 third degree lacerations in 9170 deliveries at the Lincoln Hospital, New York, New York, from January, 1942 to July, 1947. Of these, 50 were classified as complete in that the rectum itself was lacerated. The remainder were classified as incomplete as only the sphincter was involved. In the latter group, 142 of the patients with third-degree lacerations had median episiotomies, 14 had medial lateral episiotomies, and 3 patients had none.

Third-degree lacerations must be repaired immediately following this accident. Fine catgut sutures are recommended. The essential points are the closure of the rectal wound, anatomical repair of the lacerated sphincter muscle, and routine episiotomy repair. The postoperative care is simple and consists of the use of a low residue diet, mineral oil, and oil retention enemas after the third day.

Of the 159 patients, there were 26 who ran a moderately morbid course, yet the infection in no way affected wound healing. There was only one perineum that healed poorly. Three patients developed symptoms requiring secondary surgical repair. Nineteen patients had subsequent deliveries at this hospital. There was no recurrence.

JOHN R. WOLFF, M.D.

MISCELLANEOUS

Plasma Volume and Extravascular Fluid Volume During Pregnancy and the Puerperium
 LIAM L. CATON, CHARLES C. ROBY, DUNCAN E. REID, and JOHN G. GIBSON, II, *Am J Obst*, 1949, 57: 471

The purpose of this study was to investigate the changes that occur during normal pregnancy in the circulating red cell mass, and in plasma and extravascular fluid volumes. Results of the simultaneous determinations of plasma volume and extravascular fluid volume are presented.

Ten subjects were used in this study, and from 6 to 12 observations were made on each. Plasma volume was measured by using the blue dye T 1824. Extracellular fluid was measured by the use of intravenous 5 per cent sodium thiocyanate. Observations were made at 5 to 6 week intervals during pregnancy, close to the onset of labor, during the puerperium, and from 1 to 3 months postpartum. The plasma volume increased markedly during pregnancy and reached a maximum volume during the sixth-eighth to fifth day prior to the onset of labor. This increase was 49 per cent compared to nonpregnant values obtained 30 days after delivery.

OBSTETRICS

This increased plasma volume decreased 25 per cent in the last weeks of pregnancy and returned to normal 30 days after delivery.

There was an increase in the extravascular fluid up to the time of onset of labor. This rate was accelerated during the last trimester, with no evidence of any prelabor decrease. In the first week of the puerperium there was a 2,500 c.c. decrease in this extravascular fluid volume. This volume, when measured from 1 to 3 months postpartum, was 59 per cent below the maximum prepartum value.

The vascular and extravascular spaces show a retention of fluid which varies in amount in each trimester of pregnancy. During the first and second trimesters, the percentage increase of plasma volume exceeds the percentage increase of extravascular fluid volume. In the last trimester, the percentage increase in extravascular fluid volume is greater than the percentage increase in plasma volume.

JOHN R. WOLFF, M.D.

Danger of Dicumarol Treatment in Pregnancy

ALFRED P. KRAUS, SAMUEL PERLOW, and KARL SINGER. *J. Am. M. Ass.*, 1949, 139: 758

The effect of continuous dicumarol administration on the intrauterine growth and development of the fetus was studied in pregnant rabbits. When given in doses which produced an "unsafe" level of prothrombin (below 10 per cent of normal) in the mother, even for not more than 2 days, the fetuses died in utero. They were small and showed conspicuous maceration of the skin and decomposition of the organ tissues. When "safe" prothrombin levels were maintained in the mother, the infant rabbits revealed an extreme decrease of their prothrombin at birth, with a definite hemorrhagic tendency. The mothers, however, did not experience excessive intra-partum or postpartum hemorrhage.

Dicumarol affects the prothrombin level of the infant to a much greater extent than that of the mother. Although animal experiments may not be directly applicable to human beings, it would appear that dicumarol treatment is not advisable in the pregnant woman, since it may seriously interfere with the normal development of the fetus or cause fetal death.

GEORGE BLINICK, M.D.

The Role of Massive Blood Transfusions in the Management of Ruptured Uterus and Other Serious Obstetric Shock

CURTIS J. LUND and FRED O. BRUMFIELD. *South. M. J.*, 1949, 42: 263

Hemorrhage and shock in obstetrics hold a comparable position to infection with regard to mortality. The authors believe that the number of deaths from hemorrhage would be greater if more accuracy was practiced in reporting cases.

They recommend the use of large volume transfusions in the treatment of hemorrhagic obstetrical emergencies. The blood loss is often very rapid and attempts at hemostasis are often retarded by the patient's condition. The requirements of the patient must be judged by her condition and not by the

amount of blood that she has already received. Case histories are cited in which transfusions of from 3,500 c.c. to 7,500 c.c. were given in the immediate treatment of shock. The lack of postoperative morbidity is influenced by the degree to which the patient's blood picture is returned to normal.

Four instances of rupture of the uterus were reported. None of these was of traumatic origin. One occurred in a premature macerated stillbirth. A second rupture in a Couvelaire uterus, with continuation of the tear into the broad ligament, occurred following abruptio placenta. The patient received 7,500 c.c. of blood and recovered.

GEORGE B. BRADBURN, M.D.

Target and Resistant Red Cells in Pregnancy, Posthemorrhagic Anemias and Blood of the Umbilical Vein

(Globuli a bersaglio e globuli resistenti in gravidanza, nelle anemie postemorragiche e nel sangue della vena ombelicale) ARTURO VALIANI. *Arch. ostet. ginec.*, 1948, 53: 258

The author used three salt solutions (0.85, 0.50, and 0.35 per cent) and thus was able to determine the amount of red cells resistant to the 0.50 per cent solution, which he called medium resistant, and the amount of red cells resistant to the 0.35 per cent solution, which he called maximum resistant. The presence or absence of target cells was determined in stained slides by studying three different parts of the preparation for 7 minutes each. The author searched for resistant and target cells in the peripheral blood of 15 healthy women, 15 normal pregnant women, and 26 women with posthemorrhagic anemia, and also in the blood of the umbilical vein of 15 placentas immediately after section of the cord. In the order given for the four different groups, the red cells resistant to the 0.50 per cent solution averaged 62.8, 50.9, 62.3, and 48.1 per cent, respectively, and the red cells resistant to the 0.35 per cent solution averaged 17, 15, 3.4, and 10.7 per cent, respectively. Target cells were absent in the first two groups and present in the last two.

The author draws the following conclusions from his study. Target cells really exist and can be easily found on prolonged examination of the preparations, although their number is small and their distribution very irregular. They are nearly always connected with an increase in the resistance of the red cells to hypotonic salt solutions, but they may also be found in cases in which the resistance of the red cells is at the limits of normal or even slightly decreased. Normal pregnancy has no influence on the target and the resistant cells, but the latter have a tendency to decrease slightly. In posthemorrhagic anemias the percentage of resistant cells is usually increased in the fraction of maximum resistance and it is easy to find target cells, although they are still scarce. The placental blood is very rich in target and maximum resistant cells, and this new property may be added to the characteristics already studied which impart to this blood a particular type differing from the blood of the circulation.

INTERNATIONAL ABSTRACTS OF SURGERY

already received antibiotics and sulfonamides without value

Cesarean hysterectomy, embryotomy, and extraperitoneal cesarean section were the available methods

The management of these cases prior to the time of the extraperitoneal operation is not condoned by the author. Unfortunately, such instances still develop and their solution previously has been a fearful one

All of these severely infected patients were treated by means of the modern extraperitoneal cesarean section. There was no maternal mortality

Ninety-one consecutive cases of extraperitoneal cesarean section are reported without a maternal mortality. In 64 patients, contraindications to transperitoneal cesarean section were present. The fetal mortality was 8.8 per cent, 9.4 per cent of the patients with infection had babies who died of infection or as the result of prolonged labor

The fact that women with the foulest of infections may be delivered safely by this method, all the while preserving the child-bearing organ, truly marks the newer technique of extraperitoneal cesarean section as a significant advance in modern obstetrics which should be recognized by all obstetricians until some simpler method, not yet known, appears to take its place

Vaginal Delivery Following Cesarean Section

HERBERT E. SCHMITZ and GEORGE R. BABA, *Am J Obst*, 1949, 57: 669

Should a patient with a history of cesarean section be subjected to an attempt at vaginal delivery? During 18 years, 51 (32.4 per cent) of 157 patients with a history of cesarean section were successfully delivered via the vaginal route at the Lewis Memorial Maternity Hospital, Chicago, Illinois. Three instances of ruptured uteri occurred, but not in the patients subjected to a trial of labor. In these 3 cases, the rupture occurred close to term. In 2 cases the fetus was saved, and there was no maternal mortality or morbidity

Vaginal delivery may be permitted under certain conditions when the management is under an experienced obstetrician at a hospital equipped to meet all emergencies. These conditions are: (1) early engagement of the presenting parts, (2) a history of vaginal delivery preceding the section, (3) the diagnosis of a fetal death or a monstrosity in utero, and (4) reasonable assurance of a well healed scar (when the surgical technique is known to be good and the postoperative course was uneventful and afebrile). This, plus the absence of the original indication for section, will indicate a trial of labor

In these 86 vaginal deliveries following 51 cesarean sections, labor and the puerperium were uneventful. There were 3 fetal deaths, an intrauterine death before labor, death of an 8 weeks old premature infant with hydrops fetalis, and death of a 10 weeks old premature 3 pound infant. The dictum "Once

a cesarean section always a cesarean section" should be changed to "Once a cesarean section, not necessarily always a cesarean section"

JOHN R. WOLFF, M.D.

PUERPERIUM AND ITS COMPLICATIONS

A Report on 159 Third-Degree Lacerations. HAROLD A. INGRAHAM, MILTON M. GARDNER, and E. GEORGE HEUS, *Am J Obst*, 1949, 57: 730

There were 159 third degree lacerations in 9,170 deliveries at the Lincoln Hospital, New York, New York, from January, 1942 to July, 1947. Of these, 59 were classified as complete in that the rectum itself was lacerated. The remainder were classified as incomplete as only the sphincter was involved. In the latter group, 142 of the patients with third-degree lacerations had median episiotomies, 14 had mediolateral episiotomies, and 3 patients had none. Third-degree lacerations must be repaired immediately following this accident. Fine catgut sutures are recommended. The essential points are the closure of the rectal wound, anatomical repair of the lacerated sphincter muscle, and routine episiotomy repair. The postoperative care is simple and consists of the use of a low residue diet, mineral oil, and oil retention enemas after the third day

Of the 159 patients, there were 26 who ran a moderately morbid course, yet the infection in no way affected wound healing. There was only one perineum that healed poorly. Three patients developed symptoms requiring secondary surgical repair. Nineteen patients had subsequent deliveries at this hospital. There was no recurrence

MISCELLANEOUS

Plasma Volume and Extravascular Fluid Volume During Pregnancy and the Puerperium. WILLIAM L. CATON, CHARLES C. ROBY, DUNCAN E. REID, and JOHN G. GIBSON, II, *Am J Obst*, 1949, 57: 471

The purpose of this study was to investigate the changes that occur during normal pregnancy in the circulating red-cell mass, and in plasma and extravascular fluid volumes. Results of the simultaneous determinations of plasma volume and extravascular fluid volume are presented

Ten subjects were used in this study, and from 6 to 12 observations were made on each. Plasma volume was measured by using the blue dye T 1824. Extracellular fluid was measured by the use of intravenous 5 per cent sodium thiocyanate. Observations were made at 5 to 6 week intervals during pregnancy, close to the onset of labor, during the puerperium, and from 1 to 3 months postpartum. The plasma volume increased markedly during pregnancy and reached a maximum volume during the sixty-eighth to fifth day prior to the onset of labor. This increase was 49 per cent compared to nonpregnant values obtained 30 days after delivery

OBSTETRICS

This increased plasma volume decreased 25 per cent in the last weeks of pregnancy and returned to normal 30 days after delivery.

There was an increase in the extravascular fluid up to the time of onset of labor. This rate was accelerated during the last trimester, with no evidence of any prelabor decrease. In the first week of the puerperium there was a 2,500 c.c. decrease in this extravascular fluid volume. This volume, when measured from 1 to 3 months postpartum, was 59 per cent below the maximum prepartum value. The vascular and extravascular spaces show a retention of fluid which varies in amount in each trimester of pregnancy. During the first and second trimesters, the percentage increase of plasma volume exceeds the percentage increase of extravascular fluid volume. In the last trimester, the percentage increase in extravascular fluid volume is greater than the percentage increase in plasma volume.

JOHN R. WOLFF, M.D.

Danger of Dicumarol Treatment in Pregnancy

ALFRED P. KRAUS, SAMUEL PERLOW, and KARL SINGER. *J. Am. M. Ass.*, 1949, 139: 758

The effect of continuous dicumarol administration on the intrauterine growth and development of the fetus was studied in pregnant rabbits. When given in doses which produced an "unsafe" level of prothrombin (below 10 per cent of normal) in the mother, even for not more than 2 days, the fetuses died in utero. They were small and showed conspicuous maceration of the skin and decomposition of the organ tissues. When "safe" prothrombin levels were maintained in the mother, the infant rabbits revealed an extreme decrease of their prothrombin at birth, with a definite hemorrhagic tendency. The mothers, however, did not experience excessive intra-partum or postpartum hemorrhage.

Dicumarol affects the prothrombin level of the infant to a much greater extent than that of the mother. Although animal experiments may not be directly applicable to human beings, it would appear that dicumarol treatment is not advisable in the pregnant woman, since it may seriously interfere with the normal development of the fetus or cause fetal death.

GEORGE BLINICK, M.D.

The Role of Massive Blood Transfusions in the Management of Ruptured Uterus and Other Serious Obstetric Shock

CURTIS J. LUND and FRED O. BRUMFIELD. *South M. J.*, 1949, 42: 263

Hemorrhage and shock in obstetrics hold a comparable position to infection with regard to mortality. The authors believe that the number of deaths from hemorrhage would be greater if more accuracy was practiced in reporting cases. They recommend the use of large volume transfusions in the treatment of hemorrhagic obstetrical emergencies. The blood loss is often retarded by attempts at hemostasis are often retarded by the patient's condition. The requirements of the patient must be judged by her condition and not by the

amount of blood that she has already received. Case histories are cited in which transfusions of from 3,500 c.c. to 7,500 c.c. were given in the immediate treatment of shock. The lack of postoperative morbidity is influenced by the degree to which the patient's blood picture is returned to normal. Four instances of rupture of the uterus were reported. None of these was of traumatic origin. One occurred in a premature macerated stillbirth. A second rupture in a Couvelaire uterus, with continuation of the tear into the broad ligament, occurred following abruptio placenta. The patient received 7,500 c.c. of blood and recovered.

Target and Resistant Red Cells in Pregnancy, Posthemorrhagic Anemias and Blood of the Umbilical Vein (Globuli a bersaglio e globuli resistenti in gravidanza, nelle anemie postemorragiche e nel sangue della vena ombelicale)

ARTURO VALIANI
Arch. ostet. gin., 1948, 53: 258

The author used three salt solutions (0.85, 0.50, and 0.35 per cent) and thus was able to determine the amount of red cells resistant to the 0.50 per cent solution, which he called medium resistant, and the amount of red cells resistant to the 0.35 per cent solution, which he called maximum resistant. The presence or absence of target cells was determined in stained slides by studying three different parts of the preparation for 7 minutes each. The author searched for resistant and target cells in the peripheral blood of 15 healthy women, 15 normal pregnant women, and 26 women with posthemorrhagic anemia, and also in the blood of the umbilical vein of 15 placentas immediately after section of the cord. In the order given for the four different groups, the red cells resistant to the 0.50 per cent solution averaged 62.8, 50.9, 62.3, and 48.1 per cent, respectively, and the red cells resistant to the 0.35 per cent solution averaged 17.1, 15.3, 4.1, and 10.7 per cent, respectively. Target cells were absent in the first two groups and present in the last two.

The author draws the following conclusions from his study. Target cells really exist and can be easily found on prolonged examination of the preparations, although their number is small and their distribution very irregular. They are nearly always connected with an increase in the resistance of the red cells to hypotonic salt solutions, but they may also be found in cases in which the resistance of the red cells is at the limits of normal or even slightly decreased. Normal pregnancy has no influence on the target and the resistant cells, but the latter have a tendency to decrease slightly. In posthemorrhagic anemias the percentage of resistant cells is usually increased in the fraction of maximum resistance and it is easy to find target cells, although they are still scarce. The placental blood is very rich in target and maximum resistant cells, and this new property may be added to the characteristics already studied which impart to this blood a particular type differing from the blood of the circulation.

The target cells are undoubtedly young cells, as demonstrated by their analogies with the reticulocytes (hyper-resistance to hypotonic salt solutions, regular contours, increase in average diameter, decrease in thickness) This is confirmed by the fact of having found them in discrete amounts in the posthemorrhagic anemias, in which there is always a more or less marked medullary reaction, and in the blood of the umbilical cord in which there is always a polyglobulism through acceleration of the hemoglobin metabolism (increased hemolysis and increased formation) and deficit of oxygen in the fetus, hence there is a destruction of the older and more labile cells and an increase of the younger and more resistant cells

RICHARD KEMEL, M D

Specific Gravity, Hemoglobin, Hematocrit, and Proteins in the Blood of Fetuses in Various Months of Intrauterine Development (Peso specifico, emoglobina, ematocrito e proteine nel sangue dei feti nei vari mesi di sviluppo della vita intrauterina) G ANZISI *Arch ostet gin*, 1948, 53 373

The number of fetuses examined, especially those in the third, fourth and fifth month of development, is naturally small because of the difficulty of obtaining a living fetus in that period of development In one study, the copper sulfate gravimetric method was used to obtain the values for protein, hemoglobin, and hematocrit with a minimal quantity of blood The values obtained, although not rigorously exact, can be accepted as useful and sufficient for clinical studies, since control investigations with other methods in common use, and considered exact, have confirmed the reliability of the data reported Besides, the object of this study was only to obtain data of an orientative, general character on the variations of the protein, hematocrit, and hemoglobin in the fetal blood

Hemoglobin values obtained by the gravimetric method are 1 gm higher than those found with the Hellge method, values for the hematocrit are similarly higher, while those for the proteins are about the same as with the refractometric method, but higher than those given by the method of Kjeldhal Blood samples were taken from the umbilical cord in older fetuses and from the heart before death in younger fetuses This has made no difference in the results

The study showed that the values for the specific gravity of total blood and of plasma rose gradually from the third to the ninth month, presenting an average of 1042 for total blood and of 1015 for plasma in the third month, and averages of 1064 and 1028 3 respectively in the ninth month, the increases from month to month have no constant relationship The hemoglobin and hematocrit values exhibit a similar behavior from 11 gm per cent for hemoglobin and from 33 gm per cent for the hematocrit in the third month, there is a gradual rise to 17 9 gm per cent for hemoglobin and to 53 3 gm per cent for the hematocrit in the ninth month The protein content

risks from 2 7 gm per cent in the third month to 7 2 gm per cent in the ninth, with the greatest increases in the fourth, fifth, and sixth months in which the difference from month to month amounts to 1 2 gm per cent

The higher values for protein in the fourth month could in some way be explained by the activity of the liver and spleen, which is important in the genesis of the plasma proteins Another explanation would be the increased requirements of the new organism for its development

RICHARD KEMEL, M D

Importance of the Pelvimetry of the Inferior Strait, with Special Attention to Two New Diameters the Sacrobiparietal and the Symphyseobiparietal (L'importanza della pelvimetria dello stretto inferiore con speciale riguardo a due nuovi diametri il sacro- e il sinfisi biparietale) ROBERTO PICCOLI and GUGLIELMO LONGO *Arch ostet gin*, 1948, 53 347

With a pelvimeter similar to that of Thoms, the authors determined the normal values of the two new diameters, the height of the pubic symphysis, and the length of the bi-ischiatic diameter in 120 women The height of the symphysis was 5 cm in 60 women, and in the remaining 60 this measurement ranged from 3 to 6 5 cm, with a preponderance of from 5 to 6 5 cm The symphyseobiparietal diameter measured 5 cm in 34 women, ranged from 3 to 4 5 cm in 44 women and from 5 5 to 8 5 cm in 42 The sacrobiparietal diameter was 7 cm in 35 women, was over 7 cm in 57 women, and under 7 cm in 28 women

In flat pelves, the symphyseobiparietal diameter tended toward values below 5 cm more frequently than in normal pelves, and the bi-ischiatic diameter was shorter more often in normal than in flat pelves The sum of the normal values for the symphyseobiparietal and sacrobiparietal diameters is 12 cm (5 and 7 cm, respectively), and the authors have found a preponderance of 11 to 12 and 13 cm diameters in their cases From the practical point of view, it would be expected that in cases in which the symphyseobiparietal diameter is above 5 cm, the sacrobiparietal diameter would also be above 7 cm, but in the 42 cases in which the former was between 5 5 and 8 5 cm, the latter was equal to, above, or under 7 cm, with the same frequency This shows the importance of measuring the former diameter, since, in the usual absence of compensation by the latter, its excessive length would not only expose the patient to perineal damage, but would also influence the duration and modality of labor The theoretical importance of the symphyseobiparietal diameter is also evidenced by the fact that in 42 cases in which it was over 5 cm, the bi-ischiatic diameter was shorter than normal in 61 9 per cent of cases It follows that anybody who would take into account only the length of the latter would expose himself to the error of accepting as normal the width of the pubic arch even in cases in which

OBSTETRICS

adaptation of the suboccipital region to the pubic arch is impeded

The practical usefulness of the determination of the two new diameters for the prognosis of perineal lacerations is evidenced by a study of 68 primiparas, 18 to 30 years old, in whom delivery at term did not require any medical or surgical treatment. Perineal lesions were found in 50 per cent of the cases in which the symphysis was higher than normal, and in 37.5 per cent of those in which the height of the symphysis was normal. Nothing remarkable was learned from a comparison of the perineal lesions in women with a symphyseobiparietal diameter above normal and normal, since the incidence of lesions was 39.1 per cent in the first, and 38.4 per cent in the second. The same applies to the sacrobiparietal diameter in 16 women with this diameter shorter than normal, perineal lesions were found in 39.2 per cent and in the remaining 52 women, perineal lesions were found in 37.5 per cent.

RICHARD KEMEL, M D

A Review of 445 Pregnancies Complicated by Fibromyomas

DEAN J GRANDIN *Am J Obst*, 1949, 57:532

In a review of 20,763 obstetric admissions to the Sloane Maternity Hospital, New York, 445 patients (2.1 per cent) had complicating fibromyomas. In 258 of these the complication was rated as significant.

The average age of these patients was 32 years, and 75 per cent of the patients were over 30 years of age. Age and the degree of significance did not correlate. Parity and gravidity decreased as the significance increased. Fifty-one per cent of the patients were primigravidas. Relative infertility and fibroids seemed to go hand in hand.

The duration of labor was not increased by the fibroids. In 14 instances (3.1 per cent), premature labor was not increased above average. Malpresenta-

tions were observed with two to three times the usual incidence.

Postpartum hemorrhage developed in 19 patients, the usual incidence, but a retained placenta occurred with twice the expected incidence.

Only 5 per cent of the patients aborted. Toxemia and hypertensive disease showed the generally prevailing rates.

Enlargement of the fibroid during pregnancy is frequently but not always temporary. Only 1 of 4 fibroids evidenced degeneration.

Forty-four (10 per cent) of the patients were operated upon during their antepartum courses. Eighteen had hysterectomies. Three patients had myomectomies and, of these, only one continued to term and was terminated by cesarean section. Of 24 patients on whom myomectomies were performed, 11 subsequently became pregnant, 10 of these were delivered by section, and 1 patient delivered spontaneously.

Ninety per cent of the patients came to delivery, 247 delivered spontaneously and 155 were operative deliveries. Of the latter, 95 were cesarean sections.

Cesarean section was performed in 21.3 per cent of the patients, but the corrected rate for fibroids as a part or the whole of the indication was 12.8 per cent.

The morbidity rate was 26 per cent, three times greater than the usual rate. The morbidity rate for cesarean section plus myomectomy was less than that for cesarean hysterectomy.

There were 3 maternal deaths in 1 case death followed a therapeutic abortion and sterilization for hypertension and fibromyomas, in 2 cases death followed vaginal delivery. In the last 2 patients, fibromyomas were important causative factors. The fetal mortality was the same as the overall fetal mortality rate, yet it is noteworthy that there were no fetal deaths following cesarean section.

JOHN R. WOLFF, M D

period of years. Eliminating patients who were treated palliatively, the survey is limited to 115 cases in which the diagnosis was confirmed by operation or at autopsy.

Four main groups are proposed, with some detailed subgrouping. The tumors in group I are derived from the excretory epithelium of the parenchyma. The major subgroup includes the "renal-celled carcinoma" embracing clear cells and granular cells with subvarieties arranged in solid cords, tubules, or papillary cysts. Both types may occur simultaneously. Tumors in group II arise from the transitional epithelium of the conductive apparatus, beginning with the distal portion of the collecting tubules. Except for a tubular tumor of the renal pyramid, the transitional epithelium is retained. With metaplasia, the epidermoid variety with keratinization and pearls, or, less frequently, the mucous glandular form may develop. Tumors in group III, derived from embryonal rests, are poorly understood genetically. The tumor make-up may vary from a homogeneous embryonal carcinoma to one with great diversity of architecture and disparity of elements. Persistence of mesonephric elements or histological transmutations, particularly muscular cells from neighboring somites, may account for this. Group IV comprises growths arising in the muscular wall of the pelvis and ureters, in the perirenal connective tissue or capsule, or invasion from other organs.

Among these 115 cases, eliminating those in which death occurred from other causes without recurrence within 5 years and those lost to follow-up without evidence of recurrence, there remain 77 "determinate" cases upon which calculations may be made. Among these there were a few, the inclusion of which were questionable. In all types there was a 35 per cent 5 year survival. Among 47 patients with renal-celled carcinomas, there were 15 survivals (32%). Only 1 of the 10 patients with transitional carcinomas survived. Of 12 patients with embryonal tumors, 3 were living.

A life expectancy graph for survival following nephrectomy in renal-celled carcinoma is presented. This includes a group of 17 patients operated upon 10 years previously, as well as 37 patients operated upon 5 years previously, with some overlapping of individual cases. It is noted that there is a fairly sharp descent in survival to the 5 year period where the rate levels off in the 10 year group at about 40 per cent until after 7 years. There is then a further sharp decline until the tenth year. It appears to the reviewer that about 25 per cent of patients have survived.

ALLAN K. SWERSIE, M.D.

Congenital Stenosis of the Ureter at Its Origin (Stenosi congenita dell'uretere all'origine) EROS BENEDINI *Arch. ital. urol.*, 1949, 23, 54

The author reports that the results of the clinical, roentgen, and laboratory studies justified the clinical diagnosis of renal lithiasis and pyonephrosis with secondary cystitis on the right side in a woman of

40 with marked anemia and debility caused by the morbid condition of her kidney. The function of the left kidney was sufficiently good to allow removal of the right kidney, and nephrectomy was proposed. At operation, the kidney was of normal size, and palpation gave the impression of numerous cavities containing calculi. The pelvis was dilated and also contained calculi. The ureter was inserted into the pelvis in the vicinity of the hilus and markedly constricted at its origin for a distance of about 1 cm. The ureter contained no calculi, and there were no adhesions, cords, constricting vessels, or causes of angulation. Nephrectomy was performed and the wound closed in layers, a drainage tube being left in its upper angle.

Section of the specimen showed numerous hydro-pyonephrotic cavities filled with calculi of yellowish gray color, hard, and the size of small cherries, the cortex was reduced in thickness especially in its lower third. The pelvis contained small calculi and turbid urine. The diagnosis was changed to calculo hydro-pyonephrosis with constriction of the juxta-pelvic part of the ureter on the right side. The ureter of cylindric form was sectioned transversely every 4 to 5 mm from its junction with the pelvis to the point where it appeared to be normal, the lumen decreased in size as it approached the pelvis, and with the decrease in size there was a gradual decrease in the thickness of its wall. Microscopic study of the ureter demonstrated that the constriction was of a congenital nature.

Partial or total stenosis of the ureter is accompanied by dilatation of the tract above the constriction. In the present case there was evident dilatation of the pelvis with damage to its wall probably due to distention of the cavity and infection of the urine. The presence of calculi is easily explained by the sojourn of urine in the hydronephrotic cavities, this has favored the implantation of bacteria and the deposition of salts resulting in the organization of calculi.

The symptomatology of the case has not shown any characteristics attributable more to the pyelorenal condition caused by the ureteral stenosis than to the presence of calculi. It was of no help to suggest the possibility of ureteral constriction. Even catheterization did not throw light on the existence of ureteral stenosis, and the delay in the appearance of dye was justified by the lithiasis discovered on roentgen examination. The relative slowness of the flow of urine from the catheter was attributable to many factors, such as obstruction of the catheter, spasm, and angulation. Unfortunately, no ascending pyelography was performed, which might have revealed the stenosis, it was thought unnecessary in view of the fact that the most apparent lesion requiring urgent treatment (lithiasis with pyonephrosis) was sufficiently demonstrated by the studies already made. However, even if the stenosis had been discovered before intervention the therapeutic indication would have been the same.

RICHARD KEMEL, M.D.

Tumors of the Ureter FRANK COLEMAN HAMM and LAWRENCE L. LAVALLE *J Urol*, Balt., 1949, 61 493

To an approximate 180 cases of ureteral tumors reported to date, the authors add 6 cases which have been observed at the Brooklyn Hospital, New York. The first case was metastatic, secondary to a carcinoma of the breast. The second case was so diagnosed by its clinical course, but it was unconfirmed by operation or autopsy. The 4 other cases were proved to be primary ureteral tumors which varied in type from a benign polyp to a very malignant papillary carcinoma. These cases are presented in clinical detail and with photographs of the gross specimens, pyeloureterograms, and tissue histology.

There are no recognized signs and symptoms characteristic of ureteral tumor. Pain and hematuria are common. In 3 of the cases pain was apparently due to urinary obstruction and in the fourth case, to extensive local metastasis. Hematuria was severe in 2 cases and mild in the other 2. Seventy-five per cent of ureteral tumors occur in the lower third of the ureter, and in approximately one-third of them the tumor protrudes from the ureteral orifice, which permits biopsy for the correct diagnosis. In other instances, repeated cystoscopic study may be necessary.

For practical purposes, all tumors of the urinary tract should be regarded as malignant. Despite origins from different germinal layers, the epithelium of the ureter and of the bladder are alike and give rise to essentially the same neoplasms. From the structural point of view, tumors may be classified as papillary, sessile, and polypoid. The first two varieties are derived from the lining epithelial structures, the papillary type being less malignant. The polypoid tumor is derived from the submucosal structures and is covered by normal epithelium.

In view of the potential malignancy, treatment should consist in early complete surgical removal. The general condition of the patient and the status of the remaining kidney so permitting, nephrectomy, ureterectomy, and excision of a cuff of the bladder should be done at the same time.

ALLAN K. SWERSIE, M D

Pedicle Graft Cutaneous Ureterostomy GEORGE W. FISH and THOMAS W. STEVENSON *J Urol*, Balt., 1949, 61 749

In the hope of producing a better functioning stoma with less tendency toward stricture formation, a 2 stage operation was devised for connecting the ureter to the skin through a pedicled graft on the lower abdomen.

The pedicle is made from a skin flap approximately 8 by 12 cm., it includes fat and subcutaneous tissue and usually is constructed on the abdominal wall just above the belt line and lateral to the rectus muscle.

At the second stage, the ureter is freed through a low lumbar incision and is brought out through a stab wound which traverses the length of the pedicle and the underlying abdominal wall.

This type of cutaneous ureterostomy has been exceptionally efficient in 3 cases. A fourth patient with bilateral ureterosigmoidostomy and rectal incontinence was provided with similar pedicled grafts in the flank areas and the short ureters were brought out through the pedicled tubes without difficulty.

ORMOND S. CULP, M D

The Technique and Results of Ureterocolic Anastomosis by the Extraperitoneal Route E. W. RICHES *Brit J Urol*, 1949, 21 51

The main cause of death after intraperitoneal transplantation of the ureters into the colon has been infection of the peritoneal cavity. This can be avoided by carrying out the actual anastomosis outside the peritoneal cavity, if leakage should occur it is not fatal. It is believed that simplicity is the key note of success in this operation, and that it is more important to avoid compression or tension on the ureter than to try and obtain a long valvular track through the intestinal wall.

The technique used is as follows: a right oblique inguinal incision about 8 inches long is made and carried down through the muscles. The peritoneum is retracted medially and the ureter is freed and divided as near the bladder as possible. An attempt is made to leave the periureteral fat attached to the ureter. The peritoneum is opened and the lowest coil of colon in the pelvis is sought and withdrawn into the wound. This coil is sutured without tension to the cut edges of the peritoneum. The actual implantation is done either by the Coffey I method, or by the Stiles technique. The wound is closed, leaving a rubber drain to the site of anastomosis. A similar procedure is carried out on the left side.

The author has used this method in 60 cases. In 45 of the patients the operation was performed for carcinoma of the bladder. There have been 5 deaths, a mortality of 8.3 per cent, 3 of these were due to uremia, 1 death was due to intestinal obstruction, and 1 to cardiac failure. JOSEPH E. MAURER, M D

Transplantation of Ureter ARTHUR JACOBS *J Urol*, Balt., 1949, 61 517

Jacobs states that tuberculous vesical contracture with a progressive diminution in the capacity of the bladder is a common sequel of renal tuberculosis, the ever-present demands of the bladder to be emptied reduce the patient to a state of chronic invalidism, and a result of the vesical contracture may be a stricture of the ureteral orifice, back pressure from the bladder, and gradual destruction of the remaining (nontuberculous) kidney. Jacobs performs a ureteral transplantation for this condition, occasionally, ureterostomy is done instead. He adheres to the Coffey I technique with care, to retroperitonealize the site of anastomosis by stitching the edge of the lateral flap of the posterior parietal peritoneum to the bowel medial to the suture line.

Twenty-five transplantations for tuberculous vesical contracture have been performed, with a mortality of 16 per cent. He does not hesitate to transplant

INTERNATIONAL ABSTRACTS OF SURGERY

period of years. Eliminating patients who were treated palliatively, the survey is limited to 115 cases in which the diagnosis was confirmed by operation or at autopsy.

Four main groups are proposed, with some detailed subgrouping. The tumors in group I are derived from the excretory epithelium of the parenchyma. The major subgroup includes the "renal-celled carcinoma" embracing clear cells and granular cells with subvarieties arranged in solid cords, tubules, or papillary cysts. Both types may occur simultaneously. Tumors in group II arise from the transitional epithelium of the conductive apparatus, beginning with the distal portion of the collecting tubules. Except for a tubular tumor of the renal pyramid, the transitional epithelium is retained. With metaplasia, the epidermoid variety with keratinization and pearls, or, less frequently, the mucous glandular form may develop. Tumors in group III, derived from embryonal rests, are poorly understood genetically. The tumor make-up may vary from a homogeneous embryonal carcinoma to one with great diversity of architecture and disparity of elements. Persistence of mesonephric elements or histological transmutations, particularly muscular cells from neighboring somites, may account for this. Group IV comprises growths arising in the muscular wall of the pelvis and ureters, in the perirenal connective tissue or capsule, or invasion from other organs.

Among these 115 cases, eliminating those in which death occurred from other causes without recurrence within 5 years and those lost to follow-up without evidence of recurrence, there remain 77 "determinate" cases upon which calculations may be made. Among these there were a few, the inclusion of which were questionable. In all types there was a 35 per cent 5 year survival. Among 47 patients with renal-celled carcinomas, there were 15 survivals (32%). Only 1 of the 10 patients with transitional carcinomas survived. Of 12 patients with embryonal tumors, 3 were living.

A life expectancy graph for survival following nephrectomy in renal celled carcinoma is presented. This includes a group of 17 patients operated upon 10 years previously, as well as 37 patients operated upon 5 years previously, with some overlapping of individual cases. It is noted that there is a fairly sharp descent in survival to the 5 year period where the rate levels off in the 10 year group at about 40 per cent until after 7 years. There is then a further sharp decline until the tenth year. It appears to the reviewer that about 25 per cent of patients have survived.

ALLAN K. SWERSIE, M D
Congenital Stenosis of the Ureter at Its Origin
(Stenosi congenita dell'uretere all'origine) EROS
Benedini Arch Ital urol, 1949, 23 54

The author reports that the results of the clinical, roentgen, and laboratory studies justified the clinical diagnosis of renal lithiasis and pyonephrosis with secondary cystitis on the right side in a woman of

40 with marked anemia and debility caused by the morbid condition of her kidney. The function of the left kidney was sufficiently good to allow removal of the right kidney, and nephrectomy was proposed. At operation, the kidney was of normal size, and palpation gave the impression of numerous cavities containing calculi. The pelvis was dilated and also contained calculi. The ureter was inserted into the pelvis in the vicinity of the hilus and markedly constricted at its origin for a distance of about 1 cm. The ureter contained no calculi, and there were no adhesions, cords, constricting vessels, or causes of angulation. Nephrectomy was performed and the wound closed in layers, a drainage tube being left in its upper angle.

Section of the specimen showed numerous hydro-pyonephrotic cavities filled with calculi of yellowish gray color, hard, and the size of small cherries, the cortex was reduced in thickness especially in its lower third. The pelvis contained small calculi and turbid urine. The diagnosis was changed to calculo-hydropyonephrosis with constriction of the calculo-pelvic part of the ureter on the right side. The ureter of cylindric form was sectioned transversely every 4 to 5 mm from its junction with the pelvis to the point where it appeared to be normal, the lumen decreased in size as it approached the pelvis, and with the decrease in size there was a gradual decrease in the thickness of its wall. Microscopic study of the ureter demonstrated that the constriction was of a congenital nature.

Partial or total stenosis of the ureter is accompanied by dilatation of the tract above the constriction. In the present case there was evident dilatation of the pelvis with damage to its wall probably due to distention of the cavity and infection of the urine. The presence of calculi is easily explained by the sojourn of urine in the hydronephrotic cavities, this has favored the implantation of bacteria and the deposition of salts resulting in the organization of calculi.

The symptomatology of the case has not shown any characteristics attributable more to the pyelorectal condition caused by the ureteral stenosis than to the presence of calculi. It was of no help to suggest the possibility of ureteral constriction. Even catheterization did not throw light on the existence of ureteral stenosis, and the delay in the appearance of dye was justified by the lithiasis discovered on roentgen examination. The relative slowness of the flow of urine from the catheter was attributable to many factors, such as obstruction of the catheter, spasm, and angulation. Unfortunately, no ascending pyelography was performed, which might have revealed the stenosis, it was thought unnecessary in view of the fact that the most apparent lesion requiring urgent treatment (lithiasis with pyonephrosis) was sufficiently demonstrated by the studies already made. However, even if the stenosis had been discovered before intervention the therapeutic indication would have been the same.

GENITOURINARY SURGERY

Tumors of the Ureter FRANK COLEMAN HAMM and LAWRENCE L. LAVALLE *J Urol*, Balt., 1949, 61: 493

To an approximate 180 cases of ureteral tumors reported to date, the authors add 6 cases which have been observed at the Brooklyn Hospital, New York. The first case was metastatic, secondary to a carcinoma of the breast. The second case was so diagnosed by its clinical course, but it was unconfirmed by operation or autopsy. The 4 other cases were proved to be primary ureteral tumors which varied in type from a benign polyp to a very malignant papillary carcinoma. These cases are presented in clinical detail and with photographs of the gross specimens, pyeloureterograms, and tissue histology.

There are no recognized signs and symptoms characteristic of ureteral tumor. Pain and hematuria are common. In 3 of the cases pain was apparently due to urinary obstruction and in the fourth case, to extensive local metastasis. Hematuria was severe in 2 cases and mild in the other 2. Seventy-five per cent of ureteral tumors occur in the lower third of the ureter, and in approximately one-third of them the tumor protrudes from the ureteral orifice, which permits biopsy for the correct diagnosis. In other instances, repeated cystoscopic study may be necessary.

For practical purposes, all tumors of the urinary tract should be regarded as malignant. Despite origins from different germinal layers, the epithelium of the ureter and of the bladder are alike and give rise to essentially the same neoplasms. From the structural point of view, tumors may be classified as papillary, sessile, and polypoid. The first two varieties are derived from the lining epithelial structures, the papillary type being less malignant. The polypoid tumor is derived from the submucosal structures and is covered by normal epithelium.

In view of the potential malignancy, treatment should consist in early complete surgical removal. The general condition of the patient and the status of the remaining kidney so permitting, nephrectomy, ureterectomy, and excision of a cuff of the bladder should be done at the same time.

ALLAN K. SWERSIE, M.D.

Pedicle Graft Cutaneous Ureterostomy GEORGE W. FISHER and THOMAS W. STEVENSON *J Urol*, Balt., 1949, 61: 749

In the hope of producing a better functioning stoma with less tendency toward stricture formation, a 2 stage operation was devised for connecting the ureter to the skin through a pedicled graft on the lower abdomen.

The pedicle is made from a skin flap approximately 8 by 12 cm., it includes fat and subcutaneous tissue and usually is constructed on the abdominal wall just above the belt line and lateral to the rectus muscle.

At the second stage, the ureter is freed through a low lumbar incision and is brought out through a stab wound which traverses the length of the pedicle and the underlying abdominal wall.

This type of cutaneous ureterostomy has been exceptionally efficient in 3 cases. A fourth patient with bilateral ureterosigmoidostomy and rectal incontinence was provided with similar pedicled grafts in the flank areas and the short ureters were brought out through the pedicled tubes without difficulty.

DAVID ROSENBLUM, M D

BLADDER, URETHRA, AND PENIS

Transurethral Resection for Neurogenic Bladder
JOHN L. EMMETT, RICHARD V. DAUT, and RANDALL G. SPRAGUE *J Urol*, Balt, 1949, 61: 244

It is now more than 80 years since it was first observed that a characteristic type of nerve disorder occurs as a complicating factor in some cases of diabetes mellitus. Among these early observations was that of a type of vesical dysfunction or paralysis that seemed to be one of the neurologic manifestations of diabetes in some cases. During the past two decades considerable interest concerning this problem has been stimulated by the studies of several investigators, among whom may be mentioned Woltman and Wilder in 1929, Jordan and Crabtree in 1935, Rudy and Muellner in 1941, and Rundles in 1945.

Woltman and Wilder stated, "Diabetic neuritis is mainly a sensory disturbance without corresponding motor impairment, pain, paresthesia and areflexia are its main characteristics. It shows also a marked predilection for the lower extremities."

By virtue of the fact that the disease involves chiefly the sensory side of the nervous system, motor disturbances as a rule are not conspicuous. The most common finding on neurologic examination is diminution or absence of the tendon reflexes in the lower extremities. Rundles found that the Achilles reflexes were absent in 81 per cent of his 125 patients with diabetic neuropathy. In 56 per cent of the same group the patellar reflexes were absent on one or both sides. Other common findings are diminution or absence of the vibratory sense at the ankles, areas of diminished or absent cutaneous sensibility to touch, and extreme muscle tenderness, especially of the muscles of the calf. The patient experiences severe pain which may be dull and aching or which may simulate the darting or lightning pains of tabes. Argyll Robertson pupils (fixed to light but reacting normally in accommodation) are present occasionally. Vesical dysfunction of varying degree may accompany the clinical syndrome.

The clinical picture suggests that the lesion involves principally the sensory portions of the peripheral nerves, the posterior roots, and possibly also the posterior columns of the spinal cord. In some instances, particularly if Argyll Robertson pupils and vesical dysfunction are present, there may be considerable difficulty in distinguishing the disorder from true tabes dorsalis of syphilitic origin. Because of the similarity of the two conditions, the term "diabetic tabes" (pseudotabes diabetica) has been coined. Tenderness of the muscles of the calf in diabetic tabes often serves to distinguish it from syphilitic tabes dorsalis. Ordinarily, there is little difficulty in distinguishing diabetic neuropathy from other forms

of true neuritis. To quote again from Woltman and Wilder: "Striking clinical dissimilarity between neuritis of diabetes and that produced by alcohol, lead, diphtheria, and other common causes of neuritis is the almost exclusive predilection in the diabetic neuritis for sensory disturbances."

In diabetic neuropathy the total protein content of the cerebrospinal fluid is frequently increased beyond the normal maximum of 40 mgm per 100 c c. It exceeded this value in 24 of 41 cases studied by Swartz at the Mayo Clinic, the values ranging from 45 to 180 mgm per 100 c c.

Clinical observations support the view that the visceral sensory nerve fibers which are components of the sensory portions of the peripheral nerves and the posterior roots may also be involved in the pathologic process. Evidence which favors this hypothesis includes such facts as deficiencies in sweating, loss of vasomotor and pilomotor control, dependent edema, and the presence of vesical dysfunction or "paralysis."

The treatment, by transurethral resection of the vesical neck, of 3 patients who had neurogenic vesical dysfunction associated with diabetes mellitus and diabetic neuropathy is reported. The atonic type of vesical dysfunction observed in these cases closely simulated that which is seen in association with tabes dorsalis of syphilitic origin. In 1 case transurethral resection of the vesical neck resulted in moderate improvement of vesical function, in this case the amount of tissue resected was not adequate for an optimal result. In the 2 other cases resection of the vesical neck resulted in restoration of essentially normal micturition.

In the absence of effective methods of therapy of the diabetic neuropathy which is responsible for the vesical dysfunction in these cases, resection of the vesical neck provides a means of improving vesical function and thereby protecting the patient against the inconvenience and hazards involved in carrying infected residual urine in the bladder.

Indications, Limitations, Technique, and Results of Bloodless Surgery (Instrumentation) in the Treatment of Vesical Calculi. Lithotripsy and Operative Endoscopy (Indicazioni, limiti, tecnica e risultati della chirurgia incruenta [strumentale] della calcolosi vescicale litotrizia ed endoscopia operatoria). FEDERICO VACCARI *Ann Ital chir*, 1948, 25: 689

Two methods of treatment of bladder stones are at the disposal of urologists: they are (1) suprapubic cystotomy, and (2) instrumentation, the latter in the form of (a) lithotripsy or (b) endoscopic surgery.

Of 229 patients with urinary calculi, 211 were men. The greatest number of male patients was in the age group between 61 and 80 years, while the women were equally distributed among various periods of life. Single calculi were predominant, but 1 patient had 75 stones. Cystitis was present in the great majority of cases and was located at the base of the bladder.

GENITOURINARY SURGERY

Instrumentation was employed in 30.8 per cent of all male patients, cystotomy in 66.6 per cent, and other procedures, such as nephrostomy, perineotomy, or endoscopic resection of the vesical neck, in 2.52 per cent. In women the corresponding figures were 66.6 per cent, 26.6 per cent, and 6.6 per cent, respectively.

Recurrences after lithotripsy were recorded only in 5 patients. The method offers the advantage of a rapid postoperative recovery. It should not be employed in young individuals with acute cystitis because an infected bladder does not stand distention well. In the presence of a neoplasm may be overlooked. The coexistence of lithotripsy and a stone also forms a contraindication to lithotripsy. The method should not be employed in the presence of a suprapubic or rectovesical fistula, fracture of the pelvis, or paraplegia. The author used this method in 63.8 per cent of patients with single stones and in 36.7 per cent with multiple stones. If vesical lithiasis is associated with hypertrophy of the prostatic gland, cystotomy is the method of choice.

JOSEPH K. NARAT, M.D.

Clinicoexperimental Study of the Action, Prolonged for Years, of Some Amines on the Bladder of Workmen (Studio clinico-sperimentale dell'azione prolungata per anni di alcune amine sulla vescica degli operai) Giorgio Di Maio *Arch ital urol*, 1949, 23, 124

For 17 years the author has followed up 902 workmen who were employed in two dye factories and were exposed to benzidine, alpha and beta naphthylamine, and aniline. Among 186 individuals examined cystoscopically he found 34 vesical tumors, of which 18 were carcinomas, 9 sessile and 7 pedunculated tumors, and 68 congestive lesions which he regarded as precancerous. Of the individuals exposed to benzidine he examined 40 per cent, and of these 25 per cent showed tumors, 40 per cent showed congestive lesions, and 35 per cent an intact bladder. Of those exposed to alphanaphthylamine he examined 70 per cent, and of these 9 per cent showed tumors, 30 per cent congestive lesions, and 60 per cent an intact bladder. Of those exposed to betanaphthylamine he has examined 80 per cent, of these 27 per cent showed tumors, 48 per cent congestive lesions, and 25 per cent an intact bladder. Of those exposed to aniline he examined 7 per cent and found 1 case of sessile tumor (2 per cent) in which electrocoagulation was done 15 years ago, it has not recurred. Observation has revealed that the tumors may appear after an exposure ranging from 3 to 26 years, and even 18 years after contact with amines has ceased.

The age of the individual at the beginning of exposure to the amines, his familial history as to cancer, and his personal pathologic history seem to be without importance as predisposing factors for the occurrence of vesical tumor. Exposure to more than one oncogenous substance does not seem to accelerate the onset of vesical carcinoma.

The author's distinction between carcinomas and sessile and pedunculated tumors is not intended as an anatomic classification, but as a simple clinical distinction. The anatomic and histologic characteristics of the carcinomas and the endoscopic morphologic appearances of the other sessile or pedunculated tumors caused by amines do not differ from those of the common bladder tumors.

In 8 cases, which finally proved to be carcinomas and which were examined for many years, the author observed the following sequence in the first stage there was intermittent congestion of the bladder, in the second stage, sessile papilloma, sometimes recurring but always curable by diathermocoagulation, and in the third stage, carcinoma.

In about one-half of the cases of tumor, subjective and objective symptoms are absent. In about one-fifth of the cases of congestive lesions, symptoms are found. In one-fifteenth of the workmen with a normal bladder, there are symptoms which are not due to a vesical lesion or to the prostatic urethra. Even recurrences of sessile and pedunculated tumors may be silent, at least in the beginning. Therefore, in the absence of symptoms it is necessary to perform cystoscopy periodically in all workmen who have been exposed to amines.

The prognosis seems to be favorable for pedunculated tumors, reserved for sessile tumors, unfavorable for nonoperative carcinomas, and reserved for operative carcinomas. Partial cystectomy was performed in 7 patients with carcinoma, 3 are living and, as 10 years have elapsed since the operation on 2 of them, these may be considered as cured. The congestive lesions are not modified by the usual local or general treatments which are given.

RICHARD KEMEL, M.D.

Mucus-Secreting Adenocarcinoma of the Bladder HERMAN L. KRETSCHMER *J Urol*, Balt., 1949, 61, 754

Primary mucus secreting adenocarcinoma of the bladder is extremely rare, resembles more common gastrointestinal tumors, and can be accepted as authentic only after other possible primary foci have been excluded by meticulous histologic study. Such a case is reported by the author and the various theories of pathogenesis are discussed.

ORMOND S. CULP, M.D.

Primary Carcinoma of the Male Urethra (Carcinoma primitivo de uretra masculina) JOSÉ MIGUEL GÓMEZ and MAURICIO FIRSTATER. *Prensa méd argent*, 1949, 36, 319

Leucoplakia of the male urethra with the resulting stricture is frequently considered the cause of cancer. Posttraumatic strictures, nonspecific urethritis, and papillary and polypoid formations are other factors frequently mentioned in the discussion of the cause of cancer of the urethra, but chronic gonorrhea constitutes the greatest factor.

The site of election of the tumor is the penile-bulbar portion of the urethra.

INTERNATIONAL ABSTRACTS OF SURGERY

Three histologic varieties of the tumor may be distinguished squamous cell epithelioma, papillary carcinoma, and columnar cell carcinoma. A secondary infection is frequent and may lead to a diffuse phlegmon of the scrotum and the perineal region.

The tumor may invade the scrotum, the corpora cavernosa and spongiosa, the perineum, the prostatic gland, and the urinary bladder.

Usually the early symptoms are those of a urethral stricture, viz, dysuria, pain at micturition and ejaculation, and urethral secretion.

The tumefaction of hard consistency is frequently accompanied by an edema, thus simulating a periurethral inflammatory process. Painful spontaneous erections are frequently recorded. Fistulas may form.

The differential diagnosis should consider tuberculosis, syphilis, polyps, and adenomas. Blood tests, roentgenograms of the chest, examinations of the sputum and of the urethral discharge urethroscopy, and biopsy help to establish the diagnosis.

In early stages a urethrectomy, with or without plastic reconstruction or cystotomy, may be considered. In more advanced stages an amputation of the penis or a total emasculation may be required. The operation should be followed by x-ray treatment. Radium should be employed only in inoperable cases.

The authors found a cancer of the urethra, 2 cm from the meatus, in a 35 year old man. A total penectomy with implantation of the bulbar urethra into the perineum, according to Groves' technique, was performed. Thirteen months after the operation the patient had no signs of recurrence.

JOSEPH K. NARAT, M.D.

GENITAL ORGANS

Extirpation of the Granulomatous Prostate REED M. NESBIT and JACK M. LYNN *J Urol*, Balt., 1949, 61: 766

While most granulomatous lesions of the prostate may be tuberculous, the authors point out that identical histologic pictures can occur in syphilis and in nonspecific granulomatous prostatitis. Exact diagnosis depends on guinea pig inoculation with the material in question before it has been fixed in formalin. Nonspecific granulomatous prostatitis, therefore, may be more common than current statistics imply. The hazard of military tuberculosis following operation on tuberculous prostates has led to conflicting recommendations in the literature. The authors, however, performed 9 operations on 7 patients with a tuberculous prostate gland without a fatality or a fistula. These procedures included 1 perineal prostatectomy, 2 suprapubic enucleations, and 6 transurethral resections. In 3 of these 7 cases, the prostate gland was the only genitourinary organ involved. When the published statistics were added to this group from the University of Michigan, it was found that 21 suprapubic operations on patients with al-

leged tuberculous prostate glands were followed by 3 deaths, and 7 transurethral resections on patients with similar glands were followed by 1 fatality.

The authors' cases are presented in detail. One of these was thought to be the first published description of a vesical neck contracture due to tuberculosis.

ORMOND S. CULP, M.D.
HUGH J. JEWETT
J Urol, Balt., 1949, 61: 277

Radical Perineal Prostatectomy

Analysis of 132 radical perineal prostatectomies for proved carcinoma, which were performed prior to May 1, 1943, revealed 54 patients with extraprostatic extension and 78 with cancer confined to the prostate gland. In properly selected cases, the 5 year survival rate (without recurrence) was 51.3 per cent and the 10 year survival rate was 28 per cent. The operative mortality was approximately 3 per cent, and the incidence of postoperative disability due to incontinence, stricture, or fistula was low.

In most instances, palpation alone was unreliable for determining the limits of the carcinoma. Microscopic extension of the tumor beyond the area of incision was common. No tumor cells were found in the lumen of the seminal vesicles or vasa but perineural lymphatics were involved frequently. The author insists that the radical operation must include wide excision of all fascial coverings of the seminal vesicles. If this step of the operation is performed properly, the seminal vesicles are never exposed.

ORMOND S. CULP, M.D.

MISCELLANEOUS

Female Urethra NORBORNE B. POWELL and ELIZA BETH B. POWELL *J Urol*, Balt., 1949, 61: 557

The Powells state that the symptomatology of the urethral syndrome is quite protean. They believe that true prostatic glands occur in some female urethras but that they are far from being a universal finding in obstructive lesions. In their series of resected cases, in which tissue was available for study, 25 per cent showed true prostatic glands. The preponderance of opinion is to the effect that they are periurethral glands in the posterior urethra which often become infected and occasionally undergo hyperplasia. The posterior urethra is a frequent source of urologic complaint and the authors studied 603 nonconsecutive private patients. The more common symptoms were bladder discomfort, referred pain, frequency, burning, urgency, and nocturia. Bladder discomfort was present in over 95 per cent of the cases and varied in severity from a mild change during micturition to an excruciating consciousness of the urinary bladder, usually gradual in onset, and recurrent in type. In 60 per cent there was referred pain to the suprapubic or groin area, thighs, hips, loins, or the lumbosacral or sacroiliac areas. At times it simulated ureteral colic. The authors advise calibration of the urethra for the differential diagnosis when pelvic pain or backache is present. Urinary frequency was complained of by

GENITOURINARY SURGERY

36 per cent of the 603 patients Urgency of urination affected 28 per cent In 9 per cent gross hematuria was a symptom

Panendoscopy demonstrated pathologic narrowing in 43 per cent of the urethras examined, a diagnosis of stricture was made in every patient in whom the urethra would not permit passage of a #20 F instrument. Periurethritis or polyps were found in 215 urethral granulations or polyps were found in 215 Urethral bulging (enfolds) were present in 53 instances

Treatment consisted of urethral dilatations, instillations, sulfonamides, and the occasional endoscopic application of silver nitrate Polyyps were treated with gentle superficial fulguration of a segment of the urethra Transurethral resection of the bladder neck was performed when the residual urine was over 3 ounces This consisted of a short quick stroke at 6 o'clock (posteriorly) as an office procedure

Histologically, Brunn's nests were found frequently in the superficial portion of the submucosa close to the epithelial lining of the urethra The authors are of the opinion that cystitis cystica and ureteritis cystica represent vacuolization and cystic degeneration of Brunn's cell nests There was no correlation between the histological picture and the clinical history

DAVID ROSENBLUM, M D

Morphological and Functional Significance of the Ureteral Sheath and the So-Called Fissure of Waldeyer (Sul significato morfologico e funzionale della guaina ureterale e della cosiddetta fessura del Waldeyer) ANTONIO RUOTOLO *Urologia*, Treviso, 1949, 4 9

Twenty ureters, in male subjects from 20 to 50 years of age, were sectioned transversely and longitudinally with the object of studying the muscular and fascial relationships of the ureter and mural, and juxtavesical portions of the ureter and urinary bladder It was found that the muscular wall of the bladder everts upward around the lower end of the ureter in the form of a muscular sheath, however, this sheath is only about 2 to 3 cm in length, that is, it is much shorter than is generally thought At the upper end the sheath loses its muscle fibers, becomes fibrous, and goes over continuously into the adventitial tissues of the ureter Between this muscular sheath of longitudinal muscle fibers and the ureteral wall of circular muscular fibers which is filled with a loose mesh of connective fibers which inferiorly passes over into the surrounding submucosa of the bladder It is believed that those who have observed this area as an empty space and designated it as the fissure of Waldeyer were looking at an artefact, produced perhaps by the method of fixing the tissues

From his studies the author believes that the loose connective tissues filling this so-called fissure of Waldeyer serves as a sliding mechanism which guarantees the independent motion of the lower end of the ureter, that it is a factor in the so-called inver-

sions of the ureters into the urinary bladder, that it protects the ureter from involvement in the inflammatory processes of the neighboring bladder mucosa, and that adhesion of the ureteral wall to the sheath, across this loose connective tissue, by means of inflammatory cicatricial processes, may account for certain disturbances of ureteral function

JOHN W BRENNAN, M D

Experimental Contribution to the Study of Chloridemia in Rabbits with Puncture of the Chloride Center (Contributo allo studio della cloruremia nei conigli punti nel centro clorurico) PASQUALE FICARA *Arch ital urol*, 1949, 23 25

The author has determined the amount of plas-matic chloride contained in the renal artery and the renal vein, respectively, of normal rabbits, of rabbits with puncture of the fourth ventricle, and of rabbits given injections of serum from animals of the second group His experiments have confirmed the existence of a saline center in the fourth ventricle, the puncture of which causes hyperchloruria which is passively transmissible through the blood serum of the animal to a normal animal and must be connected with the action of a hormone, as demonstrated by previous investigators The chloride action should not be ascribed to an increase in the rate of the circulating chloride because the concentration in the plasmatic chloride of the peripheral blood in some animals remains practically unchanged This is in agreement with the findings of Jungmann and Meyer who made some interesting observations from which they concluded that the puncture cannot cause a hyperchloruria through simple filtration, but that the two factors of increased chloride concentration in the urine without simultaneous increase of water elimination, and of higher chloride concentration in the urine than in the blood, are reconcilable only by the hypothesis of an excitation induced by puncture or interruption of the nerves

In his own experiments the author has also observed that in rabbits with puncture and in those treated with serum from these animals there is a chloride excretion which is not always accompanied by a corresponding increase in elimination of plasma While in normal rabbits the concentration of plasma shows no significant variations in the blood obtained from the marginal vein and the renal artery and vein, in punctured rabbits or in those injected with serum from punctured rabbits the plasma chloride of the renal artery is invariably lower than that of the renal vein Therefore, the action of the hormonal stimulus can take place only in the tissue interposed between the artery and vein, i e, in the functioning renal tissue, by direct stimulation of the renal cell which alone is responsible for the abundant discharge of chloride into the urine

A hypothesis to explain the hyperchloruria after puncture of the saline center is that the amount of sodium chloride resorbed is lower than normal, or that the threshold, which is rather high for chloride, is lowered To explain the higher concentration

chloride in the vein than in the artery, when it should be lower in view of the increased elimination in the urine, it must be supposed that the kidney is capable of synthesizing sodium chloride under the hormonal stimulation, as for hippuric acid, but this hypothesis requires further study. RICHARD KEMEL, M D

Streptomycin in Nontuberculous Urinary Infections CHARLES A. WELLS and RAPHAEL MARCUS
Brit J Urol, 1949, 21 68

The authors have analyzed the courses of 12 patients with nontuberculous urinary infection who were treated with streptomycin. All of the patients were followed up carefully from a bacteriological and clinical point of view, all had had previous courses of the following therapy: (1) urinary acidification for days or weeks, (2) urinary alkalization, (3) mandelic acid for 10 days, (4) sulfonamides for 10 days, and (5) penicillin, 100,000 units every 6 hours for several days.

The urine cultures in the cases treated grew one or more of the following organisms: *Bacillus coli*, *Bacillus pyocyaneus*, *Bacillus proteus*, and *Friedländer's bacillus*. The dosage of streptomycin used was 0.5 gm every 6 hours until 4 gm was given and then, 6 hours later, a final dose of 1 gm. A striking feature was the rapidity (12 to 24 hours) with which the cultures became sterile in many instances.

The results obtained were directly related to the degree of free urinary drainage. The cases in which urinary stasis supervened did not show the response as did those in which no residual urine existed. In general, all the results were considered good, and all of the group of patients in whom the surgical program had been completed but in whom a resistant infection remained showed permanent improvement amounting to a clinical cure. No toxic reactions were manifested. JOSEPH E. MAURER, M D

Right Inguinal and Iliac Sarcomatoid Myxoma Metastasized from a Previous Remote Epididymal Blastoid Phase (Di un myxoma sarcomatode inguinale e iliaco destro, metastatizzato da progressa remota fase blastica epididimaria) GIRO TARTARINI *Arch ital urol*, 1949, 23 75

A man of 61 had been subjected to orchidectomy on the right side 9 years previously for a tumor of

the epididymis which had been diagnosed histologically as a sarcoma with myxomatous evolution. It had been well until a year ago when a swelling appeared in the right inguinal region and gradually increased in size without causing any disturbance. He had not lost any weight. Examination disclosed an ovoid, irregular swelling, the size of a lemon, with its long diameter in the direction of the inguinal canal, it was covered by normal skin of hard fibrous consistency, and was apparently attached to the deep tissues. Palpation did not cause any pain. A hard mass with an irregular surface was felt in the iliac fossa.

Under spinal anesthesia, the neoplastic mass of the inguinal canal and the metastatic lymph node along the iliac vessels were removed simultaneously with some small portions of the peritoneum which were involved, but some infiltrated tissue which was fused with the iliac vein was left in place. The wound was closed in layers and the patient recovered. The histologic picture of the specimen was that of a sarcomatoid myxoma.

This form of epididymal tumor is rare. It is not difficult to understand how the tumor, which had occurred 9 years previously, reappeared after such a long interval. The tumor had a low potential of malignancy; it was a blastoid sarcoma, one of those transition forms which, in the evolution of the normal connective tissue from undifferentiated mesenchyma (completely immature sarcoma) to the various forms of adult connective tissue (benign tumors), occupy an intermediate stage. These neoplastic sarcomatous cells with myxomatous evolutive tendency and scarce anaplasia, having reached the inguinal and iliac lymph nodes undoubtedly by the lymphatic route, have taken root and become stabilized there for a long time, perhaps because of inadequate blood supply and biochemical conditions unfavorable to growth; then, the cells have started to proliferate, perhaps after reduction of the limiting and defensive forces of the organism.

By strange coincidence, the wife of the patient had been operated upon for sarcoma of the uterus a year before he was operated upon. However, although suggestive, this has no significance in the light of modern experimental cancerology.

RICHARD KEMEL, M D

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Osteitis Fibrosa Disseminata D J MACRAE *Brit M J*, 1949, 1 389

Osteitis fibrosa disseminata is a disease of unknown etiology, involving the integrity of the skeletal system. It predominates in children from 1 to 4 years of age. Many of the patients manifest icterus gravis neonatorum. Enlarged breasts, menstruation, and sexual precocity have been commonly observed in children under 4 years of age.

Deformity and fractures of the lower extremities may be the first symptoms of this disease. Any bone may be affected. The epiphyses are characteristically spared. The diaphyses, on the other hand, are notoriously involved with patchy decalcification which may subsequently undergo cystic degeneration and spontaneous fracture.

While the periosteum does not share in the cystic formation, the cortex and medullary cavity furnish the media for the bony destruction and replacement with dense osteoid fibrous tissue. The cystic cavities are, as a rule, lined with compact fibrous tissue and nests of foam cells.

The skulls of the patients may show osseous defects namely, (1) marked thickening or hyperostosis at the base, (2) obliteration of the mastoid cells and accessory sinuses (with dense bony deposit), (3) Pagetlike architectural defects, and (4) cystic rarefaction of the occipital protuberance.

The author reports a case of osteitis fibrosa disseminata observed in a man of 25 years of age with a typical history of fractures during childhood and fibrocystic bony derangement in the occiput and humerus with hyperostotic changes in the accessory sinuses.

The author further maintains that a dysfunction of the parathyroid, pituitary, and hypothalamus glands may be interrelated to this bizarre clinical entity—a fibrocystic disease of bone characterized by episodes of recrudescence and intermission.

SAMUEL L. GOVERNALE, M D

Essential Bone Cysts and Giant-Cell Bone Tumors
(Cisti essenziali e tumori delle ossa a cellule giganti)
G CATALANO *Policlinico, sez. chir.*, 1948, 55 241

One case of solitary bone cyst and 2 cases of giant-cell tumor of the bone are reported. All of the patients had suffered pathologic fractures as a result of minor trauma. The tumors developed, respectively, in the inner third of the clavicle and the upper end of the humerus in boys of 14 and 15 years of age. The clavicular tumor was resected and a tibial implant was inserted in its place. This implant healed in perfectly and 13 months later the functional capacity of the extremity was perfect. The implant had united at both ends to form a new clavicle and

had actually begun to assume a curved aspect in imitation of the normal bone. The humeral tumor was excised and the upper end of the humerus supplanted by an osseous implant composed of the whole thickness of the fibula including its head. The head was fitted into the glenoid cavity and the remnants of the joint capsule sutured around it. The muscles of the shoulder were sutured meticulously to the implant by circular catgut sutures. The lower portion of the fibular implant was wedged into the medullary cavity of the lower humeral fragment and the areas of impaction were frequently drilled through with a fine perforator. Eight months later the fibular implant had developed osseous union with the humerus and the epiphyseal head of the implant had become somewhat flattened to adapt itself to the glenoid cavity. With some aid from the scapula the movements of the arm were limited but satisfactory, even some abduction of the arm was possible.

The solitary bone cyst was found in a woman of 30 years, however, the condition had started 10 years previously as a pathologic fracture of the lower end of the left radius. At this time the cyst was curetted and the cavity packed with plaster of paris and iodoform. The condition had recurred and revealed the typical roentgenologic picture of a loculated bone cyst. The patient refused further surgery.

The author believes that curettage and plugging of the bone cavity may be permissible in the solitary bone cyst, but not in the giant cell bone tumor because of the danger of recurrence and because of the difficulty in distinguishing this tumor from malignant varieties. On the other hand, there seems to be no indication for mutilating resections, amputations, and exarticulations. An excision of the diseased portion of the bone in these cases rarely results in recurrence and the percentage of death from metastasis, even in some of the more malignant types, is not greater than that following the more radical procedures. The possibility of securing a useful limb will win the confidence of the patient and lead to earlier surgical interventions. Even in the malignant types of bone tumor, so long as the growth is still confined within the bone itself, an ample resection followed by the placing of a free autoplasmic osseous implant in the resulting defect will undoubtedly result in a worthwhile prolongation of life and social usefulness.

JOHN W. BRENNAN, M D

Conservative Therapy of Agenesis of Tibia and Fibula
Report of 5 Clinical Cases (La terapia conservatrice delle agenesie della tibia e del perone)
ROSARIO VASSALLO *Sicilia med.*, 1949, 6 10

Five cases of agenesis of the tibia and fibula are reported by the author who concludes that conservative treatment is indicated in the majority of cases, no matter whether the agenesis is partial or total.

He obtained good results with conservative surgical procedures, such as resections or synostosis. Amputations of the big toe were performed in only 2 cases, because the organs were useless from the functional point of view. When possible, a prosthesis should be tried before amputation is advised.

Hereditary factors play the greatest role in the pathogenesis of this congenital deformity. Apparently a faulty distribution of the germinal formations leads to the malformation of the lower leg.

JOSEPH K. NARAT, M D

SURGERY OF THE BONES, JOINTS MUSCLES, TENDONS, ETC

Surgery in the Treatment of Chronic Arthritis H KELIKIAN *Surg Clin N America*, 1949, 29 87

The author discusses chronic arthritis under the headings of rheumatoid arthritis, osteoarthritis, pigmented villonodular synovitis, and osteochondromatosis. The terms are defined and differentiating characteristics are listed. The surgical treatment requires the utilization of casts to immobilize joints, splints to correct deformity, traction to correct deformity, exercises to maintain motor power and mobility, and manipulation to increase mobility.

In addition to these methods, débridement of synovial adhesions within the suprapatellar pouch of the knee may be done. Joints improve with the aspiration of excess fluid and irrigation with normal saline solution. The suprapatellar pouch may be punctured to allow escape for excess fluid, and bones may be decompressed by drilling their ends. Joints are improved by arthrotomy for removal of loose bodies, removal of fluid, and erosion of incongruities. Synovectomy is frequently of value when the inflammatory stage of the joint involved is slight or quiescent. Osteotomy to correct deformity, and osteotomy to remove the patella or the end of a nonweight-bearing or avascular necrotic bone, have a place in treatment. Arthroplasty, especially in the upper limb, during a quiescent phase of at least 1 year's duration, may be helpful, in the lower limb, the hip lends itself to cup arthroplasty in the presence of good abductors and rotators. Rheumatoid hips do not do as well as osteoarthritic hips. Arthrodesis of joints which are painful is an excellent method when mobility can be sacrificed for stability. Amputation may be used as a last resort in eliminating deformities, facilitating nursing care, and lessening pain.

Rheumatoid arthritis is a systemic disease and any measure which improves the general health of the individual also improves the joints. Osteoarthritis is a local disease and the particular part involved should be treated with the methods discussed.

DANIEL H. LEVINTHAL, M D

Ruptures of Muscles and Tendons RICHEY L WAUGH, THOMAS A HATHCOCK, and J L ELLIOTT *Surgery*, 1949, 25 370

Among 60,792 hospital admissions, the authors have encountered 50 cases of ruptured biceps brachii

muscles. Acquaviva, in 1898, was the first to describe laceration of the lacertus fibrosus. Other vulnerable muscles are, in order of frequency, calf extensor of the leg, biceps brachii, Achilles tendon, extensors of the thumb and fingers, supraspinatus tendon, rectus abdominis, adductors, etc.

Biancheri maintains that rupture of the long head of the biceps is by far the most common. In his series, 96 per cent of the lacerations were confined to the long head and only 3 per cent involved the short head of the biceps. This percentage distribution likewise was observed in the present communication.

The mechanism of ruptures of tendons is not very lucid. Speculation leads to the conclusion that occupation, osteophytic growths in the floor of the bicipital groove, indirect and direct trauma, and anatomical intrinsic musculotendinous deficiencies are the precursors of ruptured muscles. Muscle fatigue tends to increase the susceptibility of tears. One patient sustained a rupture of the long head of the biceps by lifting his hat from his head. This is not inconceivable because one occasionally encounters elongation of the tendon, fraying, laceration, and edema in the bicipital groove without discernible clinical manifestations.

Rupture of the long head of the biceps occurs at two constant levels, i.e., the high and the low. The former rupture at the supraglenoid region, whereas the latter rupture at or below the level of the bicipital groove.

The symptoms are those of a sudden snap, "bunching" of the muscle in question, with a marked reduction in muscle strength. Ecchymosis may be noted 24 to 48 hours later.

Heuter's, Ludington's and Yergason's signs help to differentiate it from other lesions of the shoulder.

The treatment consists of (1) suturing the long tendon to the short head, (2) suturing the long head to the coracoid process (Perthes), (3) suturing to the humerus (Roloff), (4) suturing to the deltoid (Cotton and Morrison), and (5) suturing to the insertion of the pectoralis major (Hoffman).

SAMUEL L. GOVERNALL, M D

Spasmodic Torticollis Surgical Treatment TRACY J PUTNAM, ERNST HERZ, and GILBERT H GLASER *Arch Neurol Psychiat*, Chic., 1949, 61 240

The effect of surgical treatment in 18 cases of a total of 43 cases of spasmodic torticollis is discussed. Generally speaking, any procedure which provides emotional relaxation will produce subjective improvement. This improvement, however, may prove to be temporary.

A table "After Dandy" is included, it shows muscles involved in torticollis together with their nerve supply.

The result of surgery primarily depends upon its ability to reduce the activity of the muscles concerned. Three surgical procedures generally have been used: (1) myotomy, used as early as 1641 (this has been abandoned in favor of more effective forms of surgical treatment), (2) section of the peripheral

nerves, and (3) intradural section of the cervical roots and spinal accessory fibers

The author outlines surgical treatment in three steps as contemplated in his series

1 The Foerster-Dandy bilateral intradural section of the first three cervical nerves and of the spinal accessory fibers

2 Unilateral or bilateral section of the spinal accessory nerves in the neck

3 Keen's operation section of the posterior divisions of the cervical nerves

In the case of further progression of the disease with lordotic posture, additional denervation is indicated

The degree of improvement depends upon various factors and a physical evaluation cannot be given. Propagation of dystonic movements, the course of the disease, the part played by the platysma muscle, the psychological attitude of the patient, his emotional situation, and personality factors must all be considered. Bilateral involvement of the neck muscles with painful severe tension and little or no emotional background is considered a definite indication for surgical intervention

KENNETH SHERMAN, M D

Poliomyelitic Scoliosis (A propos des scolioses poliomyéliquies) BOPPE and QUENEAU *Rev orthop*, Par, 1949, 35 12

Deformities of the spine resulting from poliomyelitis are attributable to a disturbance of balance not only of the muscles of the trunk but also of those of the pelvic and shoulder girdles. In addition, trophic disturbances are an important factor in the production of deformities in children and adolescents, but not in adults. The author compares the foot and the spine. In children the ligaments of an affected foot are flaccid, while in adults the foot is stiff and the ligaments are firm and resistant. Similar differences can be noticed in the spine. In an adult poliomyelitic scoliosis is limited and comparable with scoliosis caused by neuromyopathies, while in a child extensive scoliosis with considerable gibbus formation is frequently observed.

In the author's material, scoliosis developed in approximately 10 per cent of all cases of poliomyelitis. American writers report a much higher frequency of scoliosis, the discrepancy being due to the fact that these authors have a tendency to consider certain severe, progressive cases to be of paralytic origin, while in France they are classified as essential scoliosis.

Only in 2 cases was the paralysis limited strictly to the muscles of the trunk.

For the purpose of discussion of the treatment, the material is divided into three groups.

A Scoliosis caused by a disturbance of the balance of the muscles of the pelvic girdle and the lower extremities. This type of scoliosis, secondary to pelvic obliquity, is relatively rare. It is usually not difficult to correct the obliquity of the pelvis, after which the scoliosis recedes spontaneously. Only in excep-

tional cases is a lumbosacral bone graft necessary. Transplantation of the insertion of the gluteus maximus muscle or a section of the trochanter may be required to correct the abduction deformity. Tenotomy of the adductors may be necessary in case of contracture of these muscles.

B Scoliosis caused by a disturbance of balance of the muscles of the shoulder girdle and the upper extremities. Orthopedic correction of this condition is very difficult and maintenance of the proper position with a brace is not very efficient. Tendon transplantation or fascioplasmic procedures are frequently required. From the cosmetic point of view, thoracic scoliosis is very deforming, but from the functional viewpoint it is less important than lumbodorsal scoliosis.

C Scoliosis caused by a disturbance of balance of the muscles of the trunk. The correction of scoliosis with an oblique pelvis is accomplished either with the "push and pull apparatus" or with a wedge jacket. In many instances abdominal fascioplasmic procedures are unavoidable, with or without a vertebral graft or spinal fusion. The author usually employs Hibb's method of fusion.

Of 33 lumbodorsal curves, 22 were on the right side. In 18 of the 27 cases of oblique pelvis, the right side was lower than the left.

JOSEPH K. NARAT, M D

Attempts at Prosthetic Reconstruction of the Hip after Resection of the Femoral Head (Essais de reconstruction prothétique de la hanche après résection de la tête fémorale) ROBERT JUDET and JEAN JUDET *J chir*, Par, 1949, 65 17

Resection of the head of the femur is performed for various conditions, the most frequent indications being chronic degenerative arthritis, and pseudarthrosis. Different methods are in use for replacement of the head. The one employed most is transplantation of the great trochanter to the shaft of the femur.

The mechanical results of these operations are not satisfactory. Although the arthritic pains are relieved in most cases, the functional success is not very good. Frequently the joint becomes more or less ankylosed, and the femur is fixed more and more in a position of adduction and flexion. But even when satisfactory mobility is preserved, the tendency toward adduction and flexion impedes walking and produces severe limping.

To reconstruct a well functioning articulation, the authors devised a prosthesis made of methyl methacrylate (acrylic). This substance is harder than bone, can easily be drilled, filed, and fashioned to any desired shape, and can be sterilized in the autoclave. It is tolerated well by the living tissue and does not cause fibrosis or cytotoxicity.

The technique of the operation is as follows.

A vertical incision 15 cm in length is made between the tensor fascia lata and the sartorius muscles. The capsule is exposed laterally to the anterior rectus. After resection of the head the acetabulum should be enlarged (and deepened in most cases) to

provide a proper receptacle for the new head. Then a hole is drilled in the stump of the epiphysis along its axis toward the great trochanter and the prosthesis is inserted. A cast is applied for 25 days.

The author discusses the advantages of this method over the Smith-Petersen operation, in which a vital humerus is molded over the remodeled femoral head.

The new method has been used in 76 cases during the last 2 years. The results were excellent. From 60 to 90 days after the operation, the patients had a flexion of at least 60 degrees. Seventy per cent of the patients obtained a flexion of 90 degrees.

Although the time interval is too brief to form a definite evaluation of the late results, no case of foreign body reaction or irritation of the surrounding tissues has occurred up to date.

WERNER M. SOLMITZ, M.D.

The Substitution of the Musculus Gluteus Maximus. A New Operative Technique. F. SPIRA.

Acta orthop. scand., 1948, 18, 19.

Two cases of spastic paralysis with impaired gluteus maximus function were treated by transplantation of the hamstring muscles. Following Silvershield's principle, the transformation of double joint muscles into single joint ones is used to substitute the hamstrings for a paralyzed gluteus maximus muscle. The insertions of the hamstrings are transplanted from the tibia and fibula to the femur, and the origin on the tuberosity of the ischium is shifted to the ilium with the help of the ligamentum sacrotuberosum.

A detailed operative technique is reported although the author states that imperfections in technique still exist. A lateral approach to the tuberosity of the ischium was tried in the first case. It was complicated by the neurovascular bundle of the gluteus maximus muscle and by the sciatic nerve. The medial approach, on the other hand, was simple and gave a clearer view. This approach is to be recommended in future. In the first case reported, the flexors were cut in the hollow of the knee and the proximal ends of the tendons were fixed first to the deep fascia and then, during the revision, to the periosteum of the femur. Genu recurvatum developed. The gluteus maximus has two main functions: it extends the thigh when its point of fixation is the pelvis, and it raises the pelvis when its point of fixation is the thigh. The latter function is exercised, supported by other muscles, such as the hamstring, when the trunk is brought from the flexed to the erect position. Should both points of insertion be points of fixation, the function of the muscles will be that of fixing the pelvis against the femur, as is the case when standing on one leg. In addition to these main functions, the lower part of the gluteus acts as an external rotator and adductor. The loss of this muscle led to severe functional damage. The commonest causes are poliomyelitis and spastic paralysis.

Postoperative examination is conducted in the following manner: the patient stands with flexed

knee and hips; the weight of the body rests on the right leg; the left knee is abducted after standing a few minutes; the patient collapses completely. After 8 weeks of immobilization the patient is able to walk and exercise.

It was amazing to see how quickly the author's patient, who had no means of direct communication, learned to extend his right knee and hip joints. He walks without assistance long distances and can stand quite firmly on the right leg and move it normally.

Lange was the first to attempt a plastic operation and use of the erector spinae. He lengthened the mobilized muscle with silk thread to the insertion of the gluteus maximus. Krauscher's method is similar. Ober and Hey Groves substituted five bits for the silk thread. Dickson transferred the tensor fasciae from the anterior to the posterior third of the ilium. Wagner and Rizzo shift the tensor fasciae sartorius, and the long head of the rectus femur as far as possible to the posterior third of the ilium.

C. LEOPOLD GOERINGER, M.D.

Metallic Osteosynthesis with Medullary Graft for Pseudarthrosis of the Tibia (Osteosynthèse métallique avec greffe médullaire pour pseudarthrose du tibia). CL. VAN DE VOORDE. *Acta orthop. scand.*, 1949, 18, 37.

A 22 year old male suffered a fracture of both bones of the left leg. The fracture was compound and was treated by continuous extension by means of external fixation. Seven months later the fibula had healed; the tibia exhibited a frank pseudarthrosis. The edges of the pseudarthrosis were freshened and shaped with a hand saw, the medullary cavity was reamed out, and an intramedullary bone graft from the tibia of the opposite limb was inserted. The operation was completed by the application of a metallic plate with 6 screws. No plaster cast was employed. A movie film of the operation was made and this was demonstrated. The patient himself, and recent genograms (taken 7 months later) showing a perfect healing of the pseudarthrosis were exhibited.

In the subsequent discussion, Sorup of Brussels suggested that the graft might better consist of a section of the tibia of the same leg, which would avoid damage to the other limb. COOPER of Brussels preferred the inlay type of graft. DEBIEUX of Montigny sur Sambre preferred the intramedullary graft but he fixes the fragments of the tibia by pseudarthrosis with screws. He does not use a plate. VERBEECK of Antwerp remarked on the curious fact that two great surgeons favor diametrically opposed methods of treatment of pseudarthrosis. PHILLIPSTON of Chicago employs the graft but without surgical fixation, he uses a plaster cast. LAMBERTON of the other hand, after freshening the pseudarthrotic surfaces, employs a simple metallic fixation without plaster cast. VERBEECK developed the method used by the author throughout a period of years and would like to add to the technique here described and cinematographically portrayed, the application

of small osteoperiosteal fragments (taken locally) to the freshened fracture site. He has employed this method in even fresh fractures.

In concluding the discussion Van de Voorde contended that the present demonstration was not intended to start a discussion on the methods of treatment of pseudarthrosis but was simply meant to present a case. Nevertheless, he maintains that the intramedullary graft is preferable to the inlay type of graft in that it does not require fixation in a plaster cast.

JOHN W. BRENNAN, M.D.

FRACTURES AND DISLOCATIONS

Clinical and Pathologic Anatomy of Fracture, Pseudarthrosis, and Malacia of Navicular Bone (Zur Klinik und pathologischen Anatomie der Naviculare-Fraktur,—Pseudarthrose und "—Malacie") J. R. ROETTNER *Helvet. chir. acta*, 1949, 16: 25

Fracture of the navicular bone is the most frequent fracture of all carpal bones. Two types of fracture may be distinguished: intra-articular and extra-articular. The first type is the most frequent one and, as a rule, it has a transverse direction. The rare extra-articular fracture, such as an avulsion of the tuberosity, is of minor importance.

The observation of 2 cases of fracture of the navicular bone attracted the author's attention to the similarity of the condition to Kienboeck's disease, or the so-called malacia of the lunate bone.

Fractures of the navicular bone show a tendency to pseudarthrosis, attributable to the intra-articular location of the fracture, participation of the cartilage in the fracture, the formation of only myelogenous, enchondral callus, the absence of periosteal callus, the poor blood supply, the inundation of the fracture line with synovial fluid, and insufficient immobilization. The failure to recognize the fracture is usually responsible for improper treatment.

The nearthrosis of the navicular bone may be primary or secondary, the latter type forming in the fibrocartilaginous myelogenous callus.

The pseudarthrosis leads to secondary conditions such as fracture of the callus, development of cysts, fibrosis of the medulla, and aseptic necrosis of bone.

From the anatomicopathologic point of view, the conclusion is justified that the necrosis or malacia of the navicular bone represents the late result of a

pseudarthrosis or nearthrosis. Therefore the term "necrosis or malacia of the navicular bone" should be given up in favor of the more appropriate term "pseudarthrosis."

The condition is the sequel of a single violent trauma or repeated minimal traumas, to which miners, farmers, and other persons engaged in heavy work are frequently exposed.

The differential diagnosis should consider inflammatory processes, such as chronic nonspecific osteomyelitis.

JOSEPH K. NARAT, M.D.

Wedge Osteotomy for Fresh Intracapsular Fractures of the Neck of the Femur ANTHONY F. DEPALMA *Ann. Surg.*, 1949, 129: 323

Inadequate immobilization of intracapsular fractures of the neck of the femur remains the all important cause of nonunion. Fifteen and one-half per cent of fractures, in a series of 102 hips, failed to unite when treated by the orthodox method. A statistical survey emanating from the Campbell Clinic disclosed a comparable percentage of failures (13.5%). Other causes of nonunion are inadequate reduction, severe initial trauma, ablation of blood supply to the proximal fragments, death of the head of the femur, and lack of impaction of fragments.

Abduction types of fractures are said to unite in 100 per cent of cases when properly treated. Adduction fractures, however, with the well known shearing mechanism provoked by the contraction of the iliofemoral muscle, may produce absorption of the femoral head in a greater percentage of cases.

To minimize torsion and shearing force at the site of fracture, in the adduction fractures, the author has devised a wedged osteotomy to convert the fracture into an abduction type of trauma. The fragments are held in a valgus position by the internal fixation with a Smith-Petersen nail.

In the postoperative management, the author allows his patients immediate ambulation with the aid of crutches.

To date, 22 patients with adduction type of transcervical fractures of the neck of the femur have been treated with no evidence of aseptic necrosis, no loss of position of fragments, and no sign of nonunion. The youngest patient was 72 and the oldest, 83 years of age. No deaths are reported in this series of cases.

SAMUEL L. GOVERNALE, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Arterial Varices A Syndrome GERALD H PRATT
Am J Surg, 1949, 77 456

It is the purpose of this article to emphasize a syndrome that has not been emphasized before. The author calls attention to a group of patients having arteriovenous anastomosis, but whose condition was diagnosed and treated erroneously for varicose veins. Because of the inaccurate diagnosis, the treatment of arterial varices is inadequate and often delayed. The arteriovenous connections are of a congenital type, the junctions being closed for many years and suddenly opening with rapid enlargement of the veins, which appears not unlike an acute varicose vein condition. Following the classical operation for varicose veins the rapidity with which the condition recurred definitely indicated that there was some other pathologic process besides incompetent valves which needed correction.

The author notes that the first symptom noticed is an increased local heat at the site of the vein, which is registerable with the hand and always with a potentiometer. There is a heaviness and some cyanosis in the part. With the limb elevated, the veins empty incompletely but never as rapidly as do the varicose veins associated with incompetent valves. The vessels fill very rapidly following reduction of the dilation by finger pressure. If the needle on a syringe of saline or sclerosing solution is introduced into one of these vessels, arterial blood will be seen entering the fluid in the syringe barrel with each heart beat.

Accurate diagnosis of this syndrome is required in order to perform the necessary surgical treatment. The author lists some important points to be observed in making the diagnosis. The veins appear suddenly and dilate rapidly. These enlarged vessels occur most often on the lateral aspect of the leg or in the popliteal space. The veins remain partially filled on elevation of the limbs. The blood in these vessels can be reduced on pressure but the veins fill more rapidly than ordinary varicose veins on a valve failure basis. Arterial bleeding is present when such vessels are opened, and this pulsation is synchronous with cardiac systole. There is an increased skin surface temperature at the point of connections.

Of the last 272 patients referred to the Vascular Clinic with a diagnosis of varicose veins of an advanced nature, the author reports that 65, or 24 per cent of the patients, were found to have arteriovenous connections of the type described. In this same group of 272 patients were 61 patients who had been operated upon before, with prompt recurrence of the varicosities. Approximately 50 per cent of the patients with recurrences had arterial connections.

Arterial varices of the type described should be treated by exposing the vein affected and its

branches, and all connections from the arterial or venous side should be dissected free and widely excised. When the saphenous vein is thus treated, a 4 inch section should be removed, and the proximal end divided at the femoral junction. Because of the tendency of these lesions to recur, the patients who have been treated should be examined at intervals of 6 months for a period of several years. If large recurrent areas are observed, resection is required. Small recurrent connections may be obliterated by the injection of a sclerosing solution.

HERBERT F THURSTON, M D

The Experimental Production of Gradual Occlusion of Large Arteries with Polythene and Tantalum F W COOPER, JR, R L ROBERTSON, P C SHEA, JR., and E W DENNIS *Surgery*, 1949, 25 184

The authors found that the use of aluminum bands as a method of producing partial occlusion of large vessels was not feasible because the vessel beneath the band becomes atrophic and erodes. The use of cellophane, wrapped about a vessel, does not produce uniformly a complete occlusion of the vessel. The resulting reaction is a profound cellular response, with phagocytic mononuclear cells interspersed among fibrous tissue cells. This fibrocollagenous layer becomes partially hyalinized, with progressive constriction of the vessel.

Experimental procedures were undertaken to utilize a combination of these two methods of occlusion of large vessels, each of which has disadvantages. A method was sought which would lead to a gradual and complete occlusion of the vessel, and produce a moderate amount of perivascular reaction, but which would not involve surrounding structures in a fibroblastic process. To accomplish these results, a combination of the cellophane reaction and an initial partial occlusion by a tantalum band was used.

After partial occlusion of the aorta was produced by the use of a tantalum band, subsequent complete occlusion resulted from the fibroblastic cellular response produced by polythene. A double thickness of 1.5 ml polythene was placed about the aorta as a band 1.5 cm in width. A Matas band, 1 cm in width, made of tantalum was superimposed upon the polythene about the aorta, and tightened. This resulted in approximately a 60 per cent reduction in cross sectional area. The layers of polythene extended a little beyond the edge of the tantalum band, preventing contact between the tantalum and the aorta.

Through the use of the metallic band it was possible to use smaller quantities of polythene to produce a more rapid occlusion of the vessel, and to reduce the extent of the perivascular reaction. The fibrosis produced by the polythene may serve to prevent erosion of the vessel wall by the margin of

the metallic band The vessel beneath the metallic band continues to atrophy, but the entire area is encased in a sheath of fibrous tissue, which acts also as a preventive of aneurysmal formation

By this method, therefore, a partial occlusion of the artery is immediately produced by the metallic band, and the period of time required for complete occlusion of the artery is greatly decreased

SAMUEL KAHN, M D

BLOOD, TRANSFUSION

Venous Thrombosis and Anticoagulants K P BALL and H O HUGHES *Brit M J*, 1949, *i* 560

A study of 100 cases of venous thrombosis in which anticoagulant therapy was required is presented Of these, 42 per cent were on the medical service, 35 per cent on the obstetrical service, and 22 per cent on the surgical service Bauer, in 1946, showed by phlebography that venous thrombosis always arises in the deep veins of the lower leg

It is probable that only the freshly formed thrombosis breaks off If the clotting process can be halted, organization of the clot on to the vein wall will occur

Thrombosis of the leg occurred in 74 of the 100 patients An interesting sidelight relates to the follow-up study conducted by Bauer, also in 100 patients who had deep leg thrombosis 10 or more years previously Of these, 79 patients developed leg ulcers during the subsequent 10 years

Treatment is preventive and curative Preventive treatment consists in active exercises and anticoagulant therapy Curative treatment consists of (1) venous ligation, (2) sympathectomy, and (3) anticoagulants In the case of the fully developed white-leg, lumbar sympathetic block combined with anticoagulants is the treatment of choice

The comparative advantages and disadvantages of heparin and dicumarol are reviewed Dicumarol has the more contraindications to its use possible liver damage, renal failure, subacute bacterial endocarditis, disease with bleeding tendencies, and recent operations on the brain and spinal cord It is well to bear in mind that patients with high fever or debilitating diseases are more sensitive to the drug than others No fatalities from pulmonary embolism occurred among the 74 patients with deep leg thrombosis during treatment

The authors consider that accurate determinations of the prothrombin content are the basis of successful therapy with dicumarol A reliable laboratory technique is described An anticoagulant service for all hospitals is suggested

KENNETH SHERMAN, M D

Prothrombin A Critique of Methods for Its Determination, Their Clinical Significance BENJAMIN ALEXANDER, ANDRE DE VRIES, and ROBERT GOLDSTEIN *N England J M*, 1949, *240* 403

The present techniques of prothrombin estimation have their limitations which must be recognized in order to secure effective therapy and prevent disaster

Prothrombin is assayed by the ability of its conversion product, thrombin, to clot fibrinogen Recently, plasma factors affecting the conversion of prothrombin to thrombin have been described They probably act as accelerator or auxiliary agents These factors cannot be controlled at the present time, therefore, the results which are obtained express prothrombin activity rather than amounts of prothrombin

Most of the current analytical techniques are based upon the one-stage procedure of Quick, or the two-stage method of Warner *et al* In Quick's method the clotting time of the plasma is measured after the addition of thromboplastin and calcium This is called prothrombin time and represents the minimal interval before a clot develops In the two-stage procedure prothrombin is allowed to convert to thrombin in defibrinated and diluted plasma, this thrombin is then tested on its ability to clot a standard fibrinogen solution Sometimes the results of the two methods vary as much as 100 per cent, e g, in infants or aged plasma, dicumarolized blood, or hemophilic serum

In the one-stage method the factors which prolong the prothrombin time are (1) fibrinopenia (as in liver disease), (2) stored plasma, due to loss of a "labile factor," (3) antithrombin, (4) heparin and heparinlike substances, and (5) other inhibitors The factors that shorten the prothrombin time are (1) the accelerator globulin of Seegers, (2) the factor V of Owren, and (3) the prothrombin A of Quick

In view of the accelerators in serum, precaution is necessary against partial blood coagulation in the syringe during difficult venipuncture The thromboplastin reagents are Quick's fresh rabbit-brain extract which with normal plasma gives a prothrombin time of 11 to 12¼ seconds, but the potency of commercial preparations varies from batch to batch Other factors which may influence the prothrombin time are (1) the normal control plasma which shows a marked variation in prothrombin activity from day to day or from person to person, (2) the dilution of plasma and of thromboplastin, and (3) Russell viper venom which gives different results from brain extract

The relation between the "prothrombin time" and the "prothrombin activity," or "concentration per cent," is expressed by a curve The range between 25 and 100 per cent of prothrombin concentration corresponds to only very small increases of the prothrombin time, which results in very inaccurate readings Different dilution methods have been suggested as a means of improving the accuracy in this range

In the two stage method 1 unit of prothrombin is defined as the amount yielding 1 unit of thrombin in the presence of thromboplastin and calcium One unit of thrombin, in turn, will clot 1 c c of a standard fibrinogen solution in 15 seconds at 28°C The test plasma is defibrinated, diluted, and mixed with thromboplastin and calcium until the conversion of prothrombin to thrombin is complete Then a so-

lution of fibrinogen is added and the dilution inducing coagulation in 15 seconds is considered. From the dilution the units of prothrombin are computed.

The factors influencing the two stage procedure are (1) antithrombin, especially in the low prothrombin levels, (2) the lack of accelerator globulin of Seegers, (3) the Factor V of Owren, and (4) the lack of the "labile factor."

The sharp fluctuation of prothrombin time of dicumarolized patients is due to the many variable factors discussed, to variations in the rate of absorption and elimination of dicumarol, and to prothrombin regeneration in the liver. The recommended safe range of prothrombin time—up to 40 seconds—may be hazardous in patients with an otherwise disturbed hemostatic mechanism.

Until a simplified two stage procedure can offer the exact definition of prothrombin in units, the authors recommend the one stage procedure of Quick with the following modifications:

- 1 Standardization on a plasma pool of at least 5 normal persons
- 2 The addition of barium sulfate to plasma
- 3 The use of various dilutions
- 4 The determination of the prothrombic activity of undiluted plasma
- 5 The determination of the prothrombic activity of the serum

ARTHUR J. FESSER, M.D.

The Use of Replacement Transfusion in Diseases Other than Hemolytic Disease of the Newborn

M. BRESSIS *Blood*, 1949, 4, 324

Exsanguinotransfusion with replacement of from 85 to 90 per cent of the blood volume was performed in 190 adults and children. In many cases the replacement transfusions were repeated at intervals depending on the condition of the patient. With the present technique, the drawing and injection of blood can be done simultaneously. An adult with an average blood volume of 5 liters requires 15 liters of replacement blood of the same ABO and Rh groups, or O group blood with neutralized anti-A and anti-B agglutinins. Fresh citrated or heparinized blood is infused. A plastic catheter is inserted through a superficial vein until its tip is projected into a large vein. By means of an electrical pump which is connected to the plastic catheter, blood can be removed and delivered at the rate of 300 c.c. in 5 minutes. A single exsanguinotransfusion can be completed in 3 hours.

Replacement transfusions are especially indicated in the adult for anuric nephritis. The urea can be withdrawn at frequent intervals to enable survival and provide time for restoration of the kidney function. Replacement transfusions in 38 cases of leukemia induced remissions due to the antileukemic factor present in normal blood.

OPERATIVE SURGERY AND TECHNIQUE, POSTOPERATIVE TREATMENT

Potassium Metabolism in Connection with Operations N BLIXENKRONE MØLLER *Acta chir scand*, 1949, 97 300

The significance of disturbances of the metabolism of the intracellular ions in various medical and surgical conditions may have prompted this study of potassium metabolism in connection with operations. In "familial periodic paralysis" a fall of the serum potassium concentration has been shown to be the cause of the paralysis. In diarrhea in children, a large potassium loss has been demonstrated, which must be taken into account at the rehydration. In patients who have been aroused from diabetic coma by means of insulin and fluid treatment, fatigue and paralyzes caused by a fall of the serum potassium have been observed. In renal disorders, cardiac injury due to retention of potassium and elevation of serum potassium have been demonstrated, in other renal patients there has been increased loss of potassium with reduced serum potassium, fatigue, and paralyzes. In adrenal disorders and Cushing's syndrome, too, disturbances in the potassium metabolism develop. An elevation of the serum potassium concentration to more than 10 to 12 mEq/l (39 to 47 mgm per cent) is dangerous. Characteristic changes of the electrocardiogram, irregular action of the heart, and cardiac arrest appear. Excretion of potassium occurs exclusively through the urine, only in diarrhea the body is deprived of essential amounts in the stools. Even highly impaired kidneys can excrete potassium.

A study was made of 24 patients in whom 30 determinations had been carried out of the potassium excretion in the urine before operation. The general condition of all of the patients was good, they had been on an ordinary diet, and had not been dehydrated or had any metabolic disorders. It was recognized that a patient who has undergone operation is exposed to several influences, all of which may be assumed to affect the potassium excretion: the preoperative dose of morphine-scopolamine, the anesthesia, blood loss, operation, trauma, and the greater or smaller reduction of the water or food intake following the operation. Blood loss is followed by increased excretion of potassium. In case of tissue damage (caused by a tourniquet) potassium is liberated from the cells.

From this study, it was concluded that no risk is involved in using bank blood for transfusions. Only if many transfusions are to be given in quick succession, or in case of renal insufficiency, is it advisable to prefer fresh blood. Surgical patients to whom no parenteral fluid has been administered have greatly increased potassium excretion during the 24 hours following operation, especially during the afternoon.

This increase is due to cellular dehydration on account of the negative water balance. If adequate amounts of fluid are administered, the potassium excretion does not exceed that which corresponds to the tissue breakdown. Routine administration of K+ after operation is not necessary if only adequate amounts of fluid are given. If, on the other hand, the organism is dehydrated, it is indicated to add K+ to the intravenous fluid.

C FRED GOERINGER, M D

Observations on the Behavior of the Chlorides, Glucose, and the Proteins in Blister Fluids with Regard to Surgical Interventions (Osservazioni sul comportamento dei cloruri, del glucosio e delle proteine del liquido di bolla in rapporto all'intervento chirurgico) GIUSEPPE ZANNINI *Policlinico, sez chir*, 1948, 55 213

The sodium chloride, glucose, and protein content of the blister fluid in 50 surgical patients was determined along with contemporaneous blood values in the same individual. The blisters were induced by the 20-hour applications of 4 sq cm patches of cantharides plaster applied to the anterior outer surface of the thigh. Of these 50 subjects, 10 underwent gastroduodenal resection, 10 were thyroidectomized, 10 were operated upon for a variety of neoplastic conditions, and the remaining 20 were surgically treated for a variety of other conditions. The chlorides were determined by the method of Bang as modified by Sahli, the glucose, by the method of Hagedorn-Jensen, and the proteins, by the refractometer of Pulfrich.

The data, as visualized in a series of graphs, show that postoperative variations of sodium chloride in the blister fluid and the blood exhibit only insignificant variations from the normal. There was, as a rule, a tendency for the titer to sink with readjustment to the normal within a few days. The thyroidectomized patients, in general, showed a deeper and more lasting fall in the blood chlorides, however, this is ascribed to the hydration disturbances following the loss of thyroid function.

The effects of operation on the glucose values of the blister fluid were not very marked but did show an odd contrast. Following the operation the blood glucose usually underwent a transitory elevation, while that of the blister fluid tended to fall. However, this behavior of the fluid glucose is ascribed as much to the cellular content of the blister fluid and to the postoperative presence of febrile reactions in a number of these patients as to any effect of glucose on the general body metabolism.

The variation in the protein titer following operation was in no case of great significance. The protein of the blood tended to fall while that of the blister fluid tended to rise immediately following operation, however, the blood protein loss is as-

cribed to the shocklike effects of the operative assault on the processes of hydration, and the blister fluid protein increase has been ascribed to an increased capillary permeability

JOHN W BRENNAN, M D

A Study of Postoperative Pulmonary Atelectasis

JOHN GOODWIN *Brit J Surg*, 1949, 36 256

The author uses the following classification of postoperative pulmonary atelectases

Type 1 (a) Massive collapse of the lung There were none in his series (b) Segmental collapse

Type 2 Lobular collapse with roentgenological changes

Type 3 Lobular collapse without roentgenological changes

Sixty-three cases of postoperative chest complications were studied Sixty of the patients had some degree of pulmonary collapse, while of the remaining 3, 1 patient had congestive heart failure, 1 a right phrenic nerve palsy following operation for cervical rib, and 1 had a small pulmonary embolus A preoperative roentgenogram was usually taken and a postoperative roentgenogram with a portable apparatus was taken after 12 hours and then at 2 or 3 day intervals

In this series of 60 patients, 34 (57%) showed segmental collapse (Type 1), 8 (13%) showed lobular collapse with roentgenographic changes (Type 2), and 18 (30%) were diagnosed as having lobular collapse without detectable roentgenological changes (Type 3) Altogether 70 per cent, or 42 patients, showed roentgenological evidence of collapse It is important, however, to diagnose the cases without roentgenographic evidence of collapse The diagnosis is made on clinical grounds when from 6 to 24 hours after operation the patient develops a painful cough with scanty mucopurulent sputum, which is occasionally blood stained The temperature, respiration rate, and pulse rate are elevated, but the pyrexia is usually out of proportion to the pulse and respiration rates There may be pain of the pleuritic type over the basal areas of one or both lungs The physical signs may be slight and vary from an impaired percussion note at one or both bases with impaired air entry and basal rales, to basal rales alone, but this last finding is constant

Atelectasis occurred after 42 laparotomies and 10 hernia operations, and of the total number of patients, 58 had received a general anesthetic Twenty-nine (48%) of the patients had previous respiratory tract infection There was a slightly higher incidence of segmental collapse in the infected group The pre-existing situations consisted of previous pulmonary collapse, chronic bronchitis and emphysema, coryza, cough, and sinusitis In all instances collapse was basal, occurring in the right lung in 28 cases (47%), in the left lung in 13 cases (22%), and bilaterally in 19 (32%) The onset of the collapse was insidious in 49 (82%) and sudden in 11 (18%) of the patients Of those with a sudden onset, 72 per cent had segmental collapse

The treatment consisted of the intramuscular injection and inhalation of penicillin, postural drainage, breathing exercises, and inhalation of 5 per cent carbon dioxide With this treatment, the average duration of the segmental collapse was 16 days, of type 2 collapse, 10 days, and of type 3 collapse, 7 days

The author believes that "bronchoscopy is considered to be contraindicated unless treatment has been carried out for at least two weeks without result, or there is a suspicion of an intrabronchial neoplasm or foreign body" This appears to be a departure from the customary procedure which consists of bronchoscopy if the segmental atelectasis does not promptly disappear with intratracheal catheter aspiration LEROY J KLEINSASSER, M D

ANTISEPTIC SURGERY, TREATMENT OF WOUNDS AND INFECTIONS

Injuries and Death from Lightning M J G LYNCH and P H SHORTHOUSE *Lancet*, Lond, 1949, 1 473

Two individuals who succumbed to lightning shock were subjected to careful autopsy examination Their lungs showed numerous hemorrhages but gave no evidence of edema In both cases necrosis of the tail of the pancreas was marked while the head of the pancreas was unaffected The necrosis was of the coagulative variety and appeared to be due to the intense heat generated by the lightning shock Homogenization of the blood was noted in the small blood vessels of the brain, lung, and pancreas Varying degrees of tigrolysis were found in the cerebellum, olivary bodies, supra-chiasmatic region, caudate nucleus, and orbital cortex Groups of cells showed Nissl's degeneration, vacuolization of the cytoplasm, and rupture of the cell margin without any spatial pattern

There were 2 nonfatal casualties in the same accident One patient noted that he did not see the flash but found himself prostrate on the ground with no feeling in his legs This patient was cold and clammy with a thin rapid pulse and dilated pupils The right arm and both lower extremities were in a state of flaccid paralysis from which he recovered within a few hours Sensation preceded the recovery of motor power Two small burns were found on both feet The other victim, also, did not see the flash and lost consciousness for a period of 2 minutes, following which a natural speech stammer became temporarily accentuated

BENJAMIN G P SHAFIROFF, M D

The Treatment of Burns A B WALLACE *Brit J Plast Surg*, 1949, 1 232

The general principles of systemic and local care of burned patients are restated and emphasized, with a plea for common sense management to restore the individual to normal activity as rapidly as possible

The exposure method of local treatment is discussed, and the experiences and results of its use

during the past year for burns of all regions of the body are presented

The principles of the exposure method are (1) to expose the burn to daylight and cool ward temperature, (2) to keep the raw area dry and so prevent the multiplication of surface-contaminating organisms, (3) to immobilize the part in order to prevent invasion of the tissues by infecting micro-organisms, (4) to administer penicillin systemically to counter any tendency to general or local infection, and (5) to render nursing care as simple as possible

The burns treated have been mainly superficial and moderate in extent, the most extensive burn treated was one involving the left upper extremity, left chest and abdomen, and left lower extremity. In deep burns, pressure dressings are advocated for the first 4 days, then exposure until separation and surgical removal of the slough, thereafter the problem being of a more purely plastic nature

For superficial burns, it is thought that this method gives more rapid and favorable results

LOUIS T. BYARS, M.D.

The Management of Severe Burns W. A. COAKLEY, R. N. SHAPIRO, and G. W. ROBERTSON *Plast Reconstr Surg*, 1948, 3: 667

A burn is an injury caused by thermal, chemical, or electric heat, or by radiant energy. Various classifications have been devised to indicate the depth of burns as a guide to prognosis and therapy. The simplest and most widely used classification in this country is that which divides burns into three categories: (1) first degree, simple erythema, (2) second degree, partial destruction of the skin, but without destruction of all epithelial cells, (3) third degree, destruction of the full thickness of skin.

It is frequently impossible to estimate the depth of a burn accurately until at least a week or two has passed following the injury. Upon first observing the early lesion we may say that a burned area which is dry, hard, dead white, firm or leathery to the touch, or charred, is probably third degree. The presence of blebs or bullae, oozing of plasma, and visible corium usually indicate a second degree burn, while simple erythema is, of course, indicative of a first degree burn. Variations, however, are great and it is the authors' belief that the immediate diagnosis of depth of the burn is an estimation only.

The estimation of the proportion of skin area which has been burned is an important guide to both prognosis and therapy. Berkow's table has been used very widely for this purpose and is a convenient and simple standard.

Local pathology varies with the depth of the burn. In mild, first degree burns there is some dilatation of capillaries, arterioles, and venules with an increase in the blood flow. In more severe burns, there is capillary wall damage with a leakage of plasma into the tissue spaces. At the surface, this is manifested by blister formation and exudation from broken blisters. At a deeper level the increase in capillary permeability is marked by edema and increased lymph flow.

The processes of repair begin soon after the burn occurs. In mild burns, this consists of a return to normal of blood vessels, and absorption of the fluid in the tissue spaces. In more severe burns in which cells have been killed, the dead cells are removed by lysis and phagocytosis at the junction between living and dead cells. This results in the formation of a slough of dead tissues at the surface. This slough remains attached until the collagen fibers which connect it to living tissue are digested. Epithelization occurs from skin edges, remnants of hair follicles and deep glands, or, if the burn is severe enough, from the skin edges alone. If the dermis has been destroyed and repair occurs by ingrowth from the edges, the result may be quite imperfect because only a thin sheet of epithelium will cover the scar tissue. This scar epithelium is poorly nourished and poorly attached at its base and is subject to breakdown and damage on slight trauma.

Hemoglobinemia may be seen in deep burns of more than 10 per cent of the body area, and hemoglobinuria in deep burns of 30 per cent of the body area. These conditions result from intravascular hemolysis due to the heat of the burns, and disappear in from 24 to 72 hours. There may be a thrombocytopenia in very severe burns for several days following injury. Leucocytosis is seen early and is usually directly proportional to the severity of the burn. Rarely, severe burns show a leucopenia from the first to the sixth day.

Kidney damage is an important complication in the early course of patients with severe burns. Albumin, hemoglobin, and casts may be found in the urine. In more severe cases there may be oliguria, azotemia, and elevation of the blood nonprotein nitrogen. The changes are of the type seen in shock caused by any other mechanism and are probably due to decreased blood flow through the kidney. Intravascular hemolysis and hemoglobinemia may be a contributing factor in causing injury to the kidneys, and the histological picture of the kidneys in severe burns sometimes suggests this possibility. These changes are characterized by the presence of hemoglobin casts, epithelial casts, and necrosis of the tubules.

Liver necrosis in burns has been reported by many workers, but few cases have been reported in which bland ointments, saline solution, or dry dressings have been used. Many competent observers feel that liver damage can be attributed to tannic acid poisoning, but there is a case of liver necrosis following triple dye therapy, and the authors have seen a case of liver necrosis following treatment with sulfadiazine-triethanolamine spray.

In 1842, Curling called attention to the occurrence of intestinal tract ulceration following burns. This lesion is most likely to result in a severe, septic, third degree burn and is usually manifested by epigastric pain, melena, and hematemesis. The stomach or duodenum (or both) may be involved and hemorrhage is twice as apt to cause death as perforation. The condition is usually, but not always, fatal.

Damage of the respiratory tract, due to smoke inhalation, may be seen in burn cases. The resultant lesion is essentially a laryngotracheobronchitis which may go on to mucosal necrosis, pulmonary edema, and pneumonia.

Marked changes in nitrogen metabolism of the burned patient have been noted by a number of workers at various hospitals. Severe burns show a high output of nitrogen in the urine during the first 3 weeks, and sometimes for as long as several months. The resulting negative balance may reach the magnitude of 25 to 30 gm of nitrogen per day. The causative mechanism is not yet known, but a similar change has been demonstrated in fractures and other types of trauma. In addition to the above described urinary nitrogen loss, there may be a nitrogen loss of comparable magnitude from the surface of the burn and this latter may continue over long periods of time in extensive deep burns. The marked nitrogen losses from these two sources may result in the occurrence, in the burned patient, of severe hypoproteinemia within a few weeks' time, unless proper therapy is instituted. A continuing hypoproteinemia may cause tissue protein loss with weight loss, edema, weakness, and death from malnutrition as the end results.

Sodium chloride may be lost into the burned area as evidenced by a decrease in the plasma chloride and sodium concentration and a rise in the plasma potassium concentration. Hyperglycemia and acidosis are sometimes observed and many workers have noted an apparent depletion in vitamin metabolism.

Shock can be expected in burns which involve more than 15 per cent of the surface area of healthy adults, and more than 10 per cent of the surface of children or aged persons. The most important factor in the causation of burn shock is the loss of plasma from the circulation into the tissues of the burned area. Because of the increased blood concentration and increased peripheral resistance in burn shock, blood pressure values tend to remain close to normal in spite of markedly reduced total blood volume. Because of this, blood pressure is a poor index of the severity of the shock process in burns. Many investigators have tried to demonstrate the role of toxic substances released from burned areas in the production of shock. There may be many substances released from a burn area which can depress the circulatory system but there is no evidence that these toxins are important in causing burn shock in man. The entire picture can be accounted for by the loss of plasma into the burned area and a consequent loss of effective circulating blood volume. More sensitive and practical criteria for therapy can be found in hematocrit, hemoglobin, and serum plasma protein determinations. It has also been said that if the urine output is good, the general circulation is good. After severe shock has persisted in an individual for a long period (4 to 5 hours) it becomes irreversible. The exact mechanism in this change is a controversial point. Nevertheless, it is universally recognized that prolonged shock eventually produces a

condition wherein restoration of blood volume will no longer restore an adequate circulation for life.

The treatment of burns is constantly changing. Upon admission to the hospital the patient has his burned areas covered with a sterile sheet or sterile towels. If the patient is conscious and in pain morphine or codeine may be used to allay it. If shock is a factor, morphine is given intravenously to insure immediate absorption. A diagram is then made of the burned area on a burn chart. An attempt is made to estimate, as far as possible, both the degree and depth of an injury since such an estimate is necessary both for the prognosis and as a guide to therapy.

If shock is present, or if shock is anticipated from the extent of the burn, intravenous therapy is started. Normal saline or 5 per cent glucose in normal saline is used and plasma may be administered simultaneously or given after the electrolyte infusion has been given, depending upon the requirements of the case. The fluid that is lost from burns is similar in composition to blood plasma so it is logical to replace this fluid loss with plasma. However, there is experimental evidence that sodium ions administered as isotonic sodium chloride are of some value in preventing shock in burn cases. One thousand cubic centimeters of 5 per cent glucose in saline are probably adequate for the average adult in the first 24 hours, and there are definite dangers to overzealous administration of saline.

It should be mentioned that there is evidence to indicate that whole blood may have a rational place in the replacement therapy of burn shock. In general, plasma losses predominate in extensive second degree burns while in third degree burns there may be additional considerable loss of red cell mass.

After shock treatment has been instituted, dressings are applied to the burn. At this point a warning should be voiced against vigorous debridement which compounds shock and definitely increases morbidity. At this hospital no débridement is performed except in very grossly contaminated cases, and in those cases it takes the form of very gentle sponging with warmed saline. Blisters are left intact in all cases. These procedures as well as the dressing of the burns are carried out under sterile conditions with all personnel gowned and gloved.

Since World War II, the most popular local burn treatment has been that of pressure dressings over fine mesh gauze, either dry or impregnated with petrolatum or boric acid ointment.

The ointment dressings are applied to the burn area and are carried well beyond the obvious lesion because the actual burn is usually more extensive than its immediate appearance suggests. Over this initial layer a bulky layer of stuffed sterile gauze or sterile mechanics waste is placed and even compression is produced by the use of a firm, wide bandage or an elastic bandage. On the extremities, pressure dressings must extend distally to cover the remainder of the extremity and prevent the edema that proximal compression would otherwise cause. It is well to

SURGICAL TECHNIQUE

incorporate splints in the dressings of burns of the extremities. Many authors recommend the application of close fitting plaster of paris casts to achieve pressure and splinting. This technique is fraught with the dangers of circulatory impairment and gangrene.

Pressure dressings are not very practical in the treatment of burns of the face, head, neck, genitalia, and the anal region. These areas are merely covered with a layer of ointment and thin dressings which are changed at frequent intervals on the ward. In severe burns of the buttocks no dressing is applied, but the patient is placed on a soft sterile towel to which the ointment has been applied. Upon turning the patient another towel may be greased and laid upon the lesion.

The initial dressings on burns of the extremities or trunk are usually left unchanged for 10 to 14 days. If there is gross seepage through the dressings or if they slip, they are merely reinforced or extended without being removed. Burns of the hands and fingers present somewhat of an exception to the rule and are dressed rather frequently. Since there is such a great degree of disability as a result of prolonged immobilization of fingers, it is good practice to start a regime of daily warm saline or water baths with active finger and wrist motion at the end of the first week after injury.

The value of chemotherapy as a prophylactic measure against infection has been extensively discussed. It has been the practice at Kings County Hospital, Brooklyn, New York, to administer penicillin by the intramuscular route routinely in all deep burn cases, from the time of the initial dressing until the first redressing. In the majority of cases, this therapy has been continued until the burn was entirely epithelialized, either by natural processes or by skin grafting. Under this regime, infection has not been a serious problem at any time.

Hyperpyrexia is a serious complication which is sometimes manifested by burn cases in the first few days following the injury. It is seen most frequently in infants and children but may occur in adults in whom very large surface areas are involved. Delirium, stupor, or convulsions frequently accompany the hyperpyrexia. If the temperature of the patient remains above 106 degrees F for many hours, death will result, so energetic measures are necessary to treat this complication. Therapy includes intravenous fluids, ice-water sponge baths, and exposure to drafts.

The maintenance of a good nutritional status is a vital element in the care of the burned patient. Large quantities of fluids containing electrolytes and protein should be provided. Fluid intake should be sufficient to maintain a urinary output of between 1,000 and 1,500 c.c. daily, after the first day. When necessary, tube feedings or intravenous administration of carbohydrate protein hydrolysate mixtures may be resorted to. The importance of a high protein intake to balance the large nitrogen losses has been pointed out. It is very difficult to fulfill the

nutritional requirements of severely burned patients because of the anorexia associated with their injuries. Anemia is a fairly common complication after the second day. It is most marked in deep and extensive burns and in infants and children. Maintenance of normal hemoglobin and plasma protein levels is essential to proper healing and successful grafting.

The primary goal in full thickness burns should be the early and complete coverage with skin, and it is toward this goal that all therapy should be directed. The techniques used to produce local conditions favorable to grafting are varied. At Kings County Hospital, 70 per cent cod liver oil ointment is used until the slough has separated and the granulations are firm and pink. As soon as this highly desirable condition obtains, the cod liver oil ointment is discontinued and a dressing of nitrofurazone compound is applied to the granulations for a period of from 24 to 48 hours before grafting. This ointment is quite effective in eliminating mild surface infections which sometimes remain after separation of slough, and it also tends to inhibit the development of exuberant granulations. In treating burned children, the authors have found tub baths an effective adjunct in speeding the separating of slough and eliminating wound infections. As a rule, deep burns are ready to be grafted in 18 to 21 days when the technique described above is used.

Patients should not be grafted until their hemoglobin and plasma protein levels are relatively normal, and any considerable blood loss in the operating room should be promptly replaced.

Medium or thick split skin grafts are used to resurface third degree burn areas. The Padgett dermatome has made it possible to cut sheets of skin calibrated to even thickness from almost any part of the body in sections up to 4 inches by 8 inches. The thickness of skin which should be used is a question of surgical judgment, with which a number of factors are concerned. The thinner the split graft is cut, the more likely it is for a successful take. On the other hand, the thicker a graft is cut the less likely it is to contract badly. Again, the thinner the graft is taken, the quicker the donor site will heal. These factors must be considered together with the availability of donor sites and the thickness of those donor sites. There is considerable variation in the thickness of the more commonly used donor sites. The abdomen and inner sides of the thighs are considered rather thin skin, whereas the lateral sides of the thighs, the chest and back are covered with fairly thick skin. Women and children have relatively thinner skin than adult males. In general, at this hospital grafts are cut at 0.12 to 0.13 inch thickness for burn coverage in adults, and 0.08 to 0.10 inch thickness in young children. The area of skin which is grafted at one operation will depend upon the condition of the patient. As a rule, four drums of skin (128 square inches) are considered about the maximum amount which can be safely transferred at one operation, and in most cases it will be found expedient to limit the operation to two drums.

The technical details of the use of the dermatome and the fixation of grafts are not especially pertinent to this discussion. The authors use automobile "feeler" gauges to adjust the level of the dermatome blade and suture the graft to the recipient areas. When the granulation tissue is young and firm it is not disturbed, but when the recipient area is covered with old, exuberant granulation tissue, the granulations are stripped off down to a firm, yellow base. Bleeding is controlled by warm saline packs and the graft is then applied. Basting sutures improve the fixation of large grafts and "pie crust" incisions are sometimes used for stretching skin where large areas are denuded and donor areas are meager. When concave surfaces are grafted, it is convenient to use a gauze roll as a stent, tied firmly over the graft by sutures which have been left long for this purpose. Pressure dressings are always applied over the graft. If the graft is on an extremity or in the axilla or inguinal region, plaster of paris casts are valuable to insure immobilization of the part.

Grafts are usually redressed in 7 to 10 days, unless there is evidence of infection at an earlier date. A graft may be inspected or dressed as early as 3 days postoperatively if care is taken to avoid stripping it from its new bed, and if pressure and immobilization are reinstituted. Barring complications, dressings are left on donor areas for 2 or 3 weeks, by which time the areas have usually healed and need no further dressings.

Burns which involve the skin over or adjacent to joints require careful splinting if late, crippling complications and sequelae are to be prevented or minimized. It is these areas also which most urgently require early grafting. Severe burns of the popliteal or the antecubital regions are best held in extension to prevent flexion contractures. Severe burns of the hands and fingers can be very crippling. The most important factor in salvaging the burned hand is the early institution of a full range of active motion in daily saline baths. The latter measure should be started at the end of the first week. It must be interrupted when the part is grafted, but should be reinstituted as early as possible thereafter. During the convalescent period from burns which involve joint regions, hands, or fingers, the physiotherapy and occupational therapy departments can give valuable assistance in restoring function.

Burns may result in contractures which require corrective surgery despite splinting and early grafting because of the well known tendency of split skin grafts to contract. Surgery must be individualized to meet the needs of each specific case. As a rule pedicle or tubed flaps are the only effective means of treating neck contractures. Contractures on the face and about the eyes are often best treated with free full-thickness grafts. In some other areas, it is expedient to free the contracture surgically and to use a free thick split skin graft to surface the resulting defect.

The inability of the split skin graft to withstand prolonged trauma is another factor which may necessitate corrective measures in burn cases. Thus, it

may eventually be necessary to place full thickness grafts on fingers and over the dorsum of the hand while pressure bearing areas such as the sole of the foot and the palm of the hand may need pedicle flaps.

Contractures are not the only late sequelae of burns. Unstable scars, ulcers, and occasionally malignant lesions are noted. Old burn ulcers are treated by radical excision and grafting, but biopsies should be performed on all such ulcers before definite therapy is instituted. FRANK F. KANTHAKE, M.D.

Rapid Elimination of Eschar by the Use of Pyruvic Acid (A eliminação rápida da escara de queimaduras pelo emprego do ácido pirúvico) ARY DO CARMO RUSSO *Rev. brasil cir.*, 1949, 18, 31

Dissatisfaction with the various methods recommended for the treatment of deep burns led the author to try the pyruvic acid paste technique of Connor and Harvey. In the preparation of the paste, 800 c.c. of 7 per cent pyruvic acid are heated in a sterile vessel and, when boiling begins, 200 c.c. of the same, but unheated, solution, into which 80 gm. of starch have previously been dissolved, are slowly added while the mixture is continuously stirred with a spatula until a paste is formed. The paste has a pH of about 1.0. The burn is dressed with gauze which is impregnated by cold paste and the dressing is covered first with cellophane and then with vaselined gauze, over which a pressure dressing is applied and held in place by strips of adhesive plaster. The object of the use of cellophane and vaselined gauze is to avoid the rapid evaporation of the pyruvic acid solution. The dressing is changed on alternate days.

Application of this dressing does not require general anesthesia, in most cases it is sufficient to give a 0.05 gm. injection of morphine. After complete elimination of the eschar, and according to whether the wound is infected or not, dressings with penicillin (100,000 units in 1,000 c.c. of saline solution) or with saline solution only are applied for 2 or more days. These dressings free the wound of any remnant of pyruvic acid and make it ready to receive the grafts.

This method was used in 14 cases of second and third degree burns involving from 2 to 57 per cent of the body surface, the most extensive involvement by second degree burn being 57 per cent, and by third degree burn, 40 per cent. The intervals between the occurrence of the burn and the first application of pyruvic acid dressing ranged from 3 to 16 days. The number of dressings required to detach the eschar was usually three, and four in 2 cases. The intervals between the beginning of treatment and detachment of the eschar varied from 4 to 14 days, and those between occurrence of the burn and fall of the eschar from 11 to 22 days.

The use of the method offers the following advantages:

It is not traumatizing, does not cause great blood loss, and requires no anesthesia. It is efficient and

eliminates completely the necrotic tissues without damaging the healthy tissues. It is easy to apply and can be used without previous experience.

Delimitation of the eschar seems to be specifically due to the pH of the solution and to the capacity of the solution to furnish a constant supply of hydrogen ions for a sufficient period. The method should be started as soon as possible after the third day because by that time the tissues constituting the eschar can be considered as dead. Rapid preparation of the recipient bed with pyruvic acid avoids the appearance of infections by penicillin and sulfonamide resistant bacteria, and insures a good nutrient base for the grafts by elimination of necrotic tissues. For this reason the author has used large grafts, sometimes of whole-skin thickness, in many cases and thus obtained the best esthetic and functional results.

RICHARD KEMEL, M D

Pressure Sores in Paraplegic Patients RICHARD BATTLE *Brit J Plast Surg*, 1949, 1: 268

Most pressure sores in the paraplegic patient occur around the pelvis, the sacrum, ischial tuberosities, and greater trochanters are the bony prominences most frequently involved. The two most important factors in prophylaxis of such sores are the frequent turning of the patient and the maintenance of a good general condition. In the small percentage of sores which do not respond to conservative treatment, surgery must not be done unless the general nutritive state is good and the patient's healing capabilities are at their maximum. The following points are stressed in preparing any patient for this type of surgery: (a) the hemoglobin must be over 80 per cent and the red blood count over 4 million, (b) local infection must be eliminated, (c) a high protein diet must be given, and (d) acute urinary infection or other chronic infections must be controlled.

These lesions differ from raw burned areas in that they do not take a free graft well, and even if they did they are in such areas that a free graft would not stand up satisfactorily. A pedicled flap with a good protective layer of subcutaneous tissue must be shifted from an adjacent area in order to attain adequate healing. The donor site is then covered with a Thiersch graft. This is preceded by complete excision of the ulcer and any surrounding scar tissue, so that the recipient area is clean and vascular. General or local anesthesia may be used, but in most of the author's cases no anesthetic was necessary.

The sacral sores in this series were excised to leave a triangular raw area with its apex pointing down to the coccyx. The base line was then extended laterally with incisions which curved outward and downward on each side. Triangular flaps on each buttock were thus mobilized and the two sides of the triangular area were brought together. The resulting scar had a crossbow configuration. With lesions over the trochanters, there is rarely enough excess tissue present to permit shifting of a flap without a donor area defect. Two stages were necessary for shifting many of these flaps.

Lesions over the ischial tuberosities are frequently characterized by the formation of a bursa, followed by infection and sinus formation. The entire sinus must be dissected out and removed and the prominence of the ischial tuberosity chiselled away. The resultant bleeding may be difficult to control. The author inserts a small rubber tube deep into the wound to serve as a drain and through which he can instill penicillin or thrombin as indicated. The author states that flaps are less often necessary in this location.

Healing is always delayed in these patients and the sutures are usually left in for 2 weeks. After healing is complete, no weight bearing is allowed for at least 3 weeks.

STANLEY W. TUELL, M D

Streptomycin in Surgical Infections. Nonpulmonary Tuberculosis (Lymph Nodes, Urinary Tract, Bone, and Peritoneum) EDWIN J. POLASKI, JAMES F. CONNELL, JR., ADAM KOWALCZYK, and SAM F. SEELEY *Ann Surg*, 1949, 129: 90

The results of streptomycin treatment of 35 patients with proved tuberculous lymphadenitis were good. In 19 cases there was no sinus formation, but in the remaining 16, sinus formation with the discharge of pus was present. In 4 patients in the group without sinus formation, there was failure—1 had syphilis, 1 had scrofula of 18 years' duration, 1 had disseminated miliary lesions, and the fourth had a minimal pulmonary infection. Surgical treatment was utilized in 6 cases and the wounds healed per primam. Of the patients with sinus formation, 11 were treated without surgery and their sinuses healed. Three patients were operated upon and the wounds healed solidly. There were 2 failures in this group—one patient died during therapy for miliary tuberculosis, and in the other purpura occurred after a brief course of therapy, during which time the sinuses closed but later reopened.

Treatment of tuberculosis of the genitourinary tract with streptomycin is, for the most part, less satisfactory. Forty-six cases were studied. Eleven patients were benefited. Four had involvement of the bladder only, 7 had involvement of the bladder and kidneys, and 1 patient of the 7 also had an epididymitis. Improvement consisted of negativity of the urine cultures, and decrease of the bladder symptoms. The urograms did not change. Surgically treated patients healed well. There were 24 doubtful cases. These were patients with unilateral lesions in which streptomycin was used preoperatively and postoperatively to insure wound healing. There were no complications. Eleven patients were not benefited.

Tuberculosis of bone treated with streptomycin responds slowly. Eleven of the 24 patients had pulmonary tuberculosis as well. In 6 patients there was a definite response by bone healing, in 17 the bony lesions were unchanged, and in 1 patient destruction continued. In 18 patients there was a response in the contiguous soft tissue lesions and in the general condition of the patients.

Seventeen patients with tuberculous peritonitis, who were acutely ill, were treated with streptomycin. Eleven patients were greatly benefited, 3 were not benefited, and 2 patients died—one went progressively downhill in spite of treatment and the other died after many intestinal obstructions.

The criteria for improvement were a fall in temperature, relief of abdominal cramps and pain, decrease in abdominal distention, change in facies, improvement in appetite, and resolution of the doughy consistency of the abdomen and abdominal masses.

ARMAND D. ALBRECHT, M.D.

Bacitracin in Surgical Wound Infections EDWIN J. PULASKI and JAMES F. CONNELL, Jr. *Bull. U. S. Army M. Dep.*, 1949, 9: 141.

The results of parenteral bacitracin therapy in 26 patients with pyogenic surgical infections are presented. They were considered good in 16 patients, questionable in 3, and of no effect in 7. The dosage varied from 10,000 to 20,000 units every 3 hours to 100,000 units in a single daily dose. The best results were obtained in the treatment of cellulitis, and the poor results were attributed to bacitracin-resistant organisms.

All patients complained of pain at the site of injection, and in some a local inflammatory reaction was present. A few patients complained of malaise, nausea, and anorexia. Urinary frequency, nocturia, and pain in the lumbar region were present in 8 patients.

Eight patients had elevations of the nonprotein nitrogen on the sixth day of therapy which persisted from 2 to 14 days. Two of these patients showed a low urea clearance. The phenolsulfonphthalein output was depressed in 20 patients. The liver function and peripheral blood studies were normal. The urine in all cases became turbid after the fourth day of therapy, and albuminuria was present in all cases after the fourteenth injection. Sporadic glycosuria was noted in 12 patients. The urinary sediment con-

tained amorphous material, casts, degenerating renal epithelial cells, and red blood cells.

Since these urinary manifestations of nephrotoxicity were present in 24 of the 26 cases, it is suggested that further clinical evaluation awaits purification of the drug. ROBERT MAYO TENERY, M.D.

ANESTHESIA

The Utility of Intravenous Procaine in the Anesthetic Management of Cardiac Disturbances CHARLES L. BURSTEIN. *Anesthesiology*, 1949, 10: 133.

The efficacious results following the intravenous use of procaine in overcoming cardiac irregularities manifested during general anesthesia have led to the belief that this therapy tends to minimize the state of cardiac hyperirritability produced by general anesthesia. This belief is substantiated by the beneficial results obtained by intravenous procaine therapy used as a prophylactic measure to diminish the incidence and severity of cardiac arrhythmias which are so frequent during clinical surgical anesthesia. As a prophylactic measure, procaine was rapidly injected intravenously into adult patients immediately after the induction of surgical anesthesia with a general anesthetic agent. The dose of procaine given was between 75 and 100 mgm. in a 1 per cent solution. This procedure has been employed in more than 500 cases comprising all types of patients regardless of their preoperative cardiac status.

Case reports are presented to illustrate the intravenous use of procaine in combating cardiac disturbances during general anesthesia. The method is also recommended as a prophylactic measure to minimize cardiac disturbances during general anesthesia. Cases are reported to show that with this technique cyclopropane may be administered to patients with pre-existing cardiac disease without the manifestation of any apparent deleterious cardiovascular effects. MARY FRANCES POE, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Primary Hemangioma of the Skull A Rare Cranial Tumor B D WYKE *Am J Roentg*, 1949, 61 302

The author presents a review of the literature and a summary of all 40 of the cases so far appearing in print. To this list of 40 he adds 1 case report of his own, making a total of 41.

Primary hemangioma of the skull is most frequently found in the fourth decade of life and is three times as common in females as in males. The parietal bones are the most frequent site of its occurrence, and the frontal bones the next most common.

According to the author these cranial neoplasms always have a chronic history of a palpable, and often a visible lump. Except for the orbital and petrotympanic lesions these tumors tend to expand externally and for this reason neurological findings are unusual.

The roentgenologic feature of these tumors is a rounded area of rarefaction which has a peculiar "honeycombed" appearance, and rarely is there a surrounding zone of osteosclerosis or increased vascularity of the adjacent bone. A tangential view will often show spicules of bone radiating outward from a common center with expansion and erosion of the outer table of the vault. As the tumor grows the inner table may also be expanded but this usually lags behind the changes in the outer table.

These hemangiomas may be either the capillary or cavernous type although the majority are cavernous. They arise from one or more diploic veins and consist of large blood-filled lacunae embedded in a connective tissue matrix. These tumors are always benign.

The differential diagnosis of these lesions includes meningiomas, epidermoids, osteomyelitis, xanthomatosis, osteoporosis circumscripta, certain anemias, osteitis fibrosa cystica, benign osteomas, osteogenic sarcomas, and intracranial hemangiomas.

Treatment may be either by surgical removal or by radiation therapy. Block resection and replacement of the resulting defect with a bone graft is the preferable method of treatment in calvarial tumors. Irradiation is the best treatment for lesions involving the petrous bones.

The author concludes the article with a case report of a primary hemangioma of the frontal bone.

JOHN W HOPE M D

Plain Roentgenography in Intraspinal Protrusion of the Lumbar Intervertebral Discs A Correlation with Operative Findings A CHARLES BEGG and MURRAY A FALCONER *Brit J Surg*, 1949, 36 225

Plain roentgenography in the diagnosis of herniated intervertebral disc has usually been considered of negative value, that is, for the purpose of ruling out

other lesions which might simulate the clinical picture of a herniated disc. The authors, however, state that they are able to find changes suggestive of a herniated disc in 80 per cent of the cases and to localize the level accurately in approximately 50 per cent of the cases. They concur with other authorities in that degenerative changes of the intervertebral disc must occur before herniation takes place.

This study was based on 100 consecutive cases of surgically verified prolapse of a lumbar disc. Forty-two per cent of the herniations occurred in the midline and 58 per cent occurred laterally. Although the number of herniated discs at the fourth and at the fifth lumbar spaces was equal, it is interesting to note that there was a greater number of central discs at the fourth lumbar space, the ratio being 3 to 2, than at the fifth interspace, where the ratio was 1 to 3 in favor of lateral prolapse. Twenty per cent of the patients had multiple herniations.

The roentgenologic study consists of routine lateral and posteroanterior projections. If these films reveal the necessity of further study, oblique, angle, or stereoscopic views are taken. Since it is believed that a comparison of the different intervertebral spaces is necessary for the detection of degeneration, the patient must be placed in such a way as to show all of the lumbar intervertebral spaces in each view. This can be done by remembering that the rays pass out in a circle from the tube and by positioning the patient to permit the lumbar spines to form the arc of a circle in which the radius is the distance between the anode of the tube and the central point of the lumbar spine. In the lateral projection one of two methods may be used. The spines should be marked with a pencil and by using a piece of string and centering the tube over the third lumbar vertebra, sand bags may be placed under the hips and thoracic region to form this arc. A more convenient method, however, is the use of a cardboard pattern cut to match the appropriate arc of the circle. The same principle is applied to the anteroposterior or posteroanterior projection, which depends on whether the patient has a mild lordosis or kyphosis.

An additional study started in a late stage of the investigation consisted of roentgenography in different positions and movements. This consisted of lateral views of the lumbar spine with the back in acute flexion and in acute extension. This study proved of greatest value when the routine examination failed to reveal the probable level of the disc collapse.

Roentgenological evidence of degenerative changes were found at multiple levels of the lumbar spines in 42 cases and hence, although they were of no localizing value, it was helpful in that the verification of degeneration in these cases was indicative of the presence of the herniation. In a subgroup of 34 patients there was roentgenological evidence of degeneration

will enter into the trachea. The advantage of this method is its great simplicity, but one must scrupulously avoid anesthesia of the upper orifice of the esophagus, in which case some esophageal spill may also occur.

2 Per oral supraglottic instillation. Originally this method was performed by Lian Darbois and Navarre with a soft short cannula. They used no local anesthetic and no laryngeal mirror, and condemned it as haphazard and unreliable.

In a modified form the method later gave very satisfactory results and this is now widely employed.

The detailed technique is as follows: although some authors claim that in about 70 per cent of the cases no local anesthetic is necessary, it is better to apply it routinely. While the patient holds his tongue out the oil is instilled with the aid of a curved cannula, under direct laryngoscopic control, and dropped on the upturned face of the epiglottis. From there it flows into the valleculae, over the glossoepiglottic and aryepiglottic folds, and into the laryngeal inlet. Adequate posture is necessary during the filling of the bronchial tree by the oil.

3 Per oral translottic cannularization. This method is the same as the previous one, except in one detail, namely, that under indirect laryngoscopy a rigid Rosenthal laryngeal cannula is introduced.

4 Per oral endotracheal catheterization. Forestier, in 1926, used a soft catheter which he passed through the anesthetized larynx under indirect laryngoscopic control. Since then several variations of this method have been described, most of them making use of a single catheter and a few of an ingenious double catheter with an inflatable cuff. In the anesthetized patient this method may be used with great success.

5 Bronchoscopic method. Jackson was first to perform bronchography, in 1918, by insufflating bismuth carbonate powder through a bronchoscope. Since then the bronchoscopic method has found increasing use and is quite popular with a number of thoracic surgeons.

Its advantages are the possibilities of (a) sucking out the mucopurulent material present in the bronchi, (b) performing selective bronchography, and (c) dilating a stricture and instilling the bronchi beyond it.

T LEUCUTIA, M D

Angiocardiography in Congenital Heart Disease of Cyanotic Type with Pulmonic Stenosis or Atresia. Observations on the Tetralogy of Fallot and "Pseudo-Truncus Arteriosus." ROBERT N COOLEY, HENRY T BARNSON, and C. ROLLINS HANLON. *Radiology*, 1949, 52 329.

The diagnosis of pulmonic stenosis and particularly of the anomaly known as the tetralogy of Fallot has become more important since the surgical treatment of this condition has been established.

The authors employed angiocardiography in 75 patients with congenital heart disease of the cyanotic type. The group included instances of the tetralogy of Fallot, truncus arteriosus, pulmonary stenosis combined with tricuspid stenosis, complete transpor-

tation of the great vessels, the Eisenmenger complex, and other anomalies. The authors used a rapid changing cassette device that permitted six exposures in slightly less than 5 seconds. A 70 per cent solution of diodrast was used as the contrast media. One cubic centimeter per kilogram of body weight was given to young children, and slightly smaller doses to older children and to adults. Over 140 injections have been given by the authors to 75 patients with congenital cardiac anomalies of the cyanotic group. The ages of the subjects ranged from 8 months to 42 years. No serious reactions to the diodrast were observed, however, fatalities have been reported by other workers. Since most of the patients are children, strong sedation or general anesthesia is used. In this manner satisfactory roentgenograms can be obtained.

The authors reported their findings in 7 selected cases of the tetralogy of Fallot and 2 of "pseudo-truncus arteriosus." The advantages and shortcomings of the method in preoperative evaluation are discussed.

The authors feel that angiocardiography is a valuable technique in establishing an accurate diagnosis when employed in conjunction with clinical, laboratory, and physiological studies, such as catheterization of the heart.

RICHARD C RIFFLE, M D

Angiocardiography in Coarctation of the Aorta. E F SALÉN and TH WIKLUND. *Acta radiol*, Stockholm, 1948, 30 299.

The authors present their findings in 14 patients with coarctation of the aorta, 11 of whom were subsequently operated upon. Six of them were examined postoperatively.

Coarctation of the aorta is a malformation characterized by a constriction of the aorta at the transition between the aortic arch and the descending aorta. Two types have been described: (1) in the adult, the stenosis is situated immediately above the ligament of Botalli, and its craniocaudal extension is very short; (2) in the infant, it is believed that the stenotic portion includes the entire area between the left subclavian artery and the ligament of Botalli. There are many transitions between these two types. A stenosis of the aortic isthmus is often combined with other malformations of the aorta, especially hypoplasia of the aortic arch. Hypertrophy of the left subclavian artery is almost the rule, and a widening of the descending aorta is by no means rare. These alterations can be seen in the angiocardiographs.

In several of the cases in this group, marked hypoplasia of the aortic arch was observed, also, in nearly all of the cases the subclavian artery was considerably widened, sometimes attaining the same caliber as the aortic arch. The lesions of the arch affect chiefly the distal segment. In coarctation of the aorta in the lateral roentgen view, it runs in an almost vertical direction, or may be arched slightly forward. In some cases the stenotic portion is very short, in others the narrowing is gradual toward the maximal stenosis. The technique of the angiocardiog-

raphy employed is the same as that described by Robb and Steinberg. The injection for the examination is given in a sitting position. A rapid cassette changer is used. The anatomical conditions encountered at operation were well borne out in the angiocardigraphic findings.

FRANK L. HUSSEY, M D

Right Retrosternal Diaphragmatic Hernia (*Ernia diaframmatica retrosternale destra*) ARMANDO TATTONI *Radiol med*, Milano, 1949, 35 1

The case of a right retrosternal diaphragmatic hernia in a 58 year old farmer is reported by the author. There was no trauma recorded in the past history. For several years the patient has been complaining periodically of painful sensations at the base of the right chest, without cough, expectoration, fever, or any digestive disturbances. He came for an examination only because of a slight enlargement of his upper abdomen, of recent origin.

The results of the physical examination were entirely negative but the roentgenologic studies disclosed a right diaphragmatic hernia, through the region corresponding to Morgagni's foramen. The transverse colon formed the contents of the hernia.

Apparently the hernia was of congenital origin because no violent trauma could be found in the past history.

JOSEPH K. NARAT, M D

Diagnosis of Congenital Obstruction of the Stomach and Small Intestine in the Newborn ERIC V. BAEYER *Radiology*, 1949, 52 157

The survival of newborn infants with alimentary obstruction depends as much on prompt and accurate preoperative diagnosis as on adequate nutritional measures and expert surgery. Roentgenography provides the most accurate method of demonstrating alimentary obstructive lesions of any type.

Obstructive lesions of the esophagus and rectum are not discussed in this article. The same methods of studying obstructions in the adult are used in the study of obstructions in the infant, namely, roentgenography without the use of contrast media (flat film technique), roentgenography with the use of contrast media, fluoroscopy, fluorography (spot film technique). The methods may be used as desired. The value of flat film is wholly dependent on the presence or absence of swallowed air and its distribution. Films taken in the first 24 hours are usually less informative than those taken later, after distention has reached a marked degree. Fluid levels are of greater significance than the mere presence of gas distended loops.

It is advisable to obtain erect or inverted films in every case of suspected bowel obstruction. Oral administration of barium may become desirable although some hazards are involved. The amount of barium used should be as small as possible. A soft rubber catheter is valuable to administer the barium mixture, to remove secretion and retained food before examination, and to remove the remaining barium from the stomach after completion of the

examination. The urgency of surgical intervention may outweigh the desirability of accurate preoperative diagnosis in the matter of time entailed by barium studies. Painstaking fluoroscopy supported by spot-filming offers a distinct advantage over conventional roentgenographic procedures. Deviation from the normal anatomic position of certain segments, such as malrotation or displacement of mass lesions, and the rate of progress of the contrast meal and abnormal peristaltic phenomena are more apparent fluoroscopically than on films. Spot films are used for the permanent record of fluoroscopic observations. Hypertrophic pyloric stenosis, the most common congenital obstructive lesion of the gastrointestinal tract, is probably the only obstructive condition between the esophagus and rectum in which the clinical history and findings are usually characteristic enough to warrant surgical intervention without roentgenologic study.

The two roentgenologic signs of supportive value are palpation of a pyloric tumor under the fluoroscope, and a delay of more than 5 minutes in the opening of the pylorus. Persistent narrowing and elongation of the pyloric canal are important roentgen findings. Pyloric spasm has to be differentiated from pyloric stenosis. Conditions in the duodenum which produce obstruction are aplasia and atresia, stenosis and diaphragm, annular pancreas, peritoneal band and volvulus, aberrant vessels and duplication. In atresia and aplasia, as well as in severely stenosing annular pancreas, the characteristic hour glass configuration of the stomach and proximal segment of the duodenum may be demonstrated on flat films if these structures happen to be empty of fluid and contain a sufficient amount of air.

Differential diagnosis of congenital obstructive lesions of the jejunum and ileum involves an even greater variety of conditions than are encountered in the duodenum. In addition to lesions that occur at any level of the alimentary tract, such as aplasia, atresia, stenosis, and duplication cyst, consideration must be given to such diverse possibilities as mesenteric and omental cysts, Meckel's diverticulum with obstructing band, volvulus, herniations of various kinds, extrinsic tumors, and the important entity of pancreatic insufficiency (meconium ileus). On a clinical basis, an extrinsic etiology may be assured when a picture of incomplete obstruction is associated with a palpable tumor, a situation likely to be encountered in omental, mesenteric, or duplication cysts and tumors. Incomplete obstruction in the absence of a palpable mass should bring to mind stenosis, volvulus, or hernia. Intrinsic obstruction is usually suggested by the picture of complete occlusion. The recognition of meconium ileus, which is one of these, is facilitated by the concomitant manifestations of pulmonary disease. While thus a differentiation of extrinsic against intrinsic, and of incomplete against complete, obstruction is clinically possible to a certain degree, accurate localization of the lesion is seldom achieved owing to the unreliability of estimating the intestinal level by the

PHYSICOCHEMICAL METHODS IN SURGERY

amount of distention present. A barium enema in suspected high colonic atresia or stenosis will differentiate these lesions from low ileal obstruction. The accuracy of roentgen diagnosis of gastrointestinal obstruction in the newborn can be greatly enhanced by basing the diagnostic procedure on fluoroscopy and by making considerable use of fluorographs (spot films).

Seven cases of congenital obstruction are presented in which barium studies led to a correct diagnosis: hypertrophic pyloric stenosis, pyloric spasm, duodenal atresia, malrotation in partial duodenal obstruction, aplasia of segment of ileum, incomplete atresia of the proximal jejunum, and duplication cyst of the jejunum.

FRANK L. HUSSEY, M.D.

Bone Sarcomas (Sui sarcomi delle ossa) MAURO PIEMONTE *Radiol med*, Milano, 1949, 35 105

Various tumors may develop from connective tissue, according to its stage of evolution. Immature or ablastic sarcomas derive from nondifferentiated mesenchyma, blastic sarcomas from tissues in an intermediate stage of development, and benign tumors from adult or fully developed connective tissue.

Radiologically ablastic sarcomas greatly resemble metastases.

The author accepts the following classification of bone sarcomas, suggested by Geschickter and Cope: land primary chondromyxosarcoma, secondary chondrosarcoma, osteogenic osteoblastic sarcoma, chondroblastic sarcoma, and osteolytic osteogenic sarcoma.

Various types of bone sarcoma are illustrated by corresponding roentgenograms.

JOSEPH K. NARAT, M.D.

Arthrograms H. KELIKIAN and ELBERT KENNETH LEWIS *Radiology*, 1949, 52 465

Joint motion depends upon the integrity of the articular cavity and the smoothness of its lining. Movement is compromised when the cavity is obliterated or effaced, when it is invaded by the products of inflammation and of wear and tear, when it is encroached upon by growths, when it is partially or completely filled by fibrous, osseous, and osteocartilaginous deposits, and when the surface which line it are rough and incongruous. Information as to the contour, the content, the capacity, and the communications of the articular cavity would therefore be of value.

The authors evaluate the findings of more than 3,000 arthrograms. Air is injected into the joints with an ordinary glass syringe. The amount of air injected varies according to the joint injected. Radiographs are taken immediately after injection with an attempt to obtain the maximum amount of detail.

The knee is subjected to arthrography far more frequently than any other joint. It is a complex articulation. It contains intra articular fibrocartilages and ligaments, the articular cavity is lined by

the most extensive investment of synovial membrane and hyaline plates. Besides the vast coat of cartilage which covers the articular ends of the femur and tibia, the joint cavity receives additional lining from the articular facet of the largest sesamoid bone in the body, the patella. The fabella, a small sesamoid bone often found in the lateral head of the gastrocnemius, also offers the articular cavity has a knee a hyaline surface. The articular cavity has a large cul-de-sac above the patella, an extensive anterior chamber, and two rear compartments. The study of arthrograms has enriched the knowledge of joint anatomy and pathology. Lesions of the semilunar cartilages of the knee are demonstrated by changes in the outline of the menisci. The medial semilunar cartilage is more frequently torn than the lateral. The medial meniscus splits lengthwise, its circumferential border remaining attached to the tibial collateral ligament while the torn inner slip shifts toward the intercondyloid notch. A marginal tear of the medial meniscus is surmised when there is seen an air pocket between the tibial collateral ligament and the shifting wedge of the semilunar cartilage. Tears of the lateral meniscus seldom occur. A loosened lateral meniscus in connection with tears of the posterior cruciate, discoid cartilage, and synovial cysts along its circumferential border can not be visualized in arthrograms.

In the back of the knee a septum divides the articular cavity into two compartments. The so-called Baker's cyst or the gastrocnemio semimembranosus bursa communicates with the inner, and the diverticulum along the popliteus muscle connects with the outer compartment of the posterior knee joint. Joint outpouchings partake in the changes to which synovial lining of the main joint is heir, they contain villi, adhesions, osteocartilaginous bodies, and gain in capacity with the rest of the joint cavity as a result of repeated hydrarthrosis. Their dependent position, their twisted course around tendons and muscles, and the narrow neck which joins them with the main articular cavity, subject these diverticula to localized irritations. They become filled and distended with thick glairy exudate which will not empty and interferes with the flexion of the knee. Loose bodies formed in the main joint may gravitate into the popliteal diverticulum, usually into the one along the popliteus tendon, which connects with the joint through a wider neck. Arthrograms will reveal the size of these outpouchings, their content, and their connection with the main joint.

Arthrograms help to determine the number, location, and sometimes the source of osteocartilaginous bodies in and around the joints. Foreign bodies, such as shrapnel, present in the soft tissues close to the joint must be localized. Arthrograms will reveal whether they are intrasynovial or extrasynovial.

In rheumatoid arthritis, arthrograms give a variable picture. When villi predominate, the joint cavity gains in capacity, it contains fluid. When the intra-articular adhesions hold the upper hand, the

joint cavity will admit less air, its lining will cast a jagged contour. Shadows indicative of adhesions and irregularity of the articular contour are more characteristic of rheumatoid arthritis than those denoting villi or other projections into the articular cavity.

In pigmented villonodular synovitis, arthrograms reveal an enlarged articular cavity containing fluid. The shadow cast by the joint cavity presents a smooth contour and gives a bubbly flocculent effect due to the filling defects produced by villi and nodules.

Lipomas are recognized in arthrograms by their location in front of the knee, more commonly above than below the patella. Prefemoral lipomas may be so large as to obliterate the suprapatellar pouch completely, or they may be small and create a partial filling defect in the arthrogram. Both prefemoral and infrapatellar fat pads may contain calcific deposits simulating osteocartilaginous bodies. Filling defects of the articular cavity may also be caused by hemangioma, synovial ganglia, polyps, fibroma, and enchondroma. In the arthrogram, the shadow cast by hemangioma is dense, it is usually speckled with opacities indicative of sclerotic vessels and phleboliths. Synovial cysts and ganglia occur more often near the circumferential border of the menisci, synovial fibroma and chondroma cast denser shadows than lipomas. Synovioma is an extremely rare tumor.

Intra-articular chip fractures can be differentiated from phleboliths, osteocartilaginous bodies, the sesamoid bone, the separate center of ossification, a piece of bone pinched off by compression, or from an avulsion ossicle, by arthrograms.

FRANK L. HUSSEY, M D

The Clinical and Roentgen Manifestations of Erythroblastosis Fetalis MAX RITVO, IRVING A. SHAUFFER, and GERALD KROSINICK. *Am J Roentg*, 1949, 61: 291

Erythroblastosis fetalis is characterized by edema, jaundice, anemia, and circulating erythroblasts. Three forms of erythroblastosis fetalis are recognized: (1) hydrops fetalis, (2) icterus gravis, and (3) congenital anemia. The first-born infant is rarely involved, but usually the succeeding children of an Rh-negative mother and an Rh-positive father are found to have this condition. It occurs in about 1 birth of every 250 births.

Prompt recognition of this condition and proper therapy has reduced the fatal outcome in some instances. The authors conducted the study of the fetus in utero by roentgenographic means at the Boston City Hospital.

In hydrops fetalis, fluid is found in the soft tissues and body cavities, with enlargement of the liver and spleen, anemia, immature red cells, and a large placenta. This condition is often fatal in the intra-uterine period. Icterus gravis is usually associated with jaundice at the time of birth or within the first 24 hours, but rarely later. Progressive anemia, pul-

monary hemorrhage, or injury to the brain result in death. Survival may occur with proper therapy in many cases of this variety. Congenital anemia is the mildest and least frequent type. Extreme pallor is the only sign, and blood studies reveal large numbers of immature red cells.

The authors give a brief discussion on the Rh factors and their interaction. Most cases of erythroblastosis fetalis are due to immunization of the mother to Rh₀. Rh agglutinins are formed by the mother as a result of transfusion with Rh positive blood or transmission of Rh positive fetal red cells into the maternal circulation; the agglutinins then traverse the placenta to produce agglutination and hemolysis of the fetal erythrocytes.

Blood studies in suspected cases should consist of typing of both parents and anti-Rh-titer estimations in the mother. The absence of Rh antibodies usually means that the infant will be normal, while the presence of Rh antibodies in the mother during pregnancy indicates the probable occurrence of erythroblastosis fetalis. During pregnancy, antibody titers should be recorded at frequent intervals after the seventh month of pregnancy. If an Rh-negative mother first presents antibodies less than 10 weeks antepartum, spontaneous labor is probably advisable. If antibodies appear during the tenth to fourteenth week antepartum, early induction should be considered. The presence of antibodies 14 or more weeks antepartum is suggestive of serious injury to the fetus.

Soft tissue changes are seen roentgenographically. They occur with massive edema which causes marked swelling and tissue thickening of the head, face, and chin, and produces a halolike appearance. In many cases the extremities are clearly seen. The splenic and hepatic enlargement is not seen in utero.

A marked increase in the density may be seen in the skull, vertebrae, ribs, and pelvis. In the skull, the sphenoid and occipital bones are principally involved. The pelvis and other flat bones may be diffusely eburnated. The long bones show a uniformly increased density with narrowing or obliteration of the medullary spaces. These abnormalities may be demonstrated in utero.

Fetal death occurs frequently. This results in overlapping of the skull bones. Sharp angulation of the head in relation to the spine, lordosis of the caudal extremity of the spinal column, collapse of the thoracic cage, and generalized decalcification of the fetal skeleton are also signs of fetal death.

The authors point out the difficulty in obtaining such information in utero and have outlined their roentgen technique. Four case reports are presented with the reproductions of 15 roentgenograms.

HORACE G. BUTLER, M D

Interstitial Calcinosis (Sulla calcinosi interstiziale) G. F. TESTA and A. GRIGNANI. *Radiol med*, Milano, 1949, 35: 163

Interstitial calcinosis has been variously designated as the syndrome of Thibierge-Weissenbach,

syndrome of Profichet, syndrome of Minkowski, calcium gout, calcareous diathesis, circumscribed petrification of the skin, calcareous rheumatic tendino fascitis, calcareous tendinitis, universal calcinosis universalis, and cutaneous stone

The reported case, that of a man, was studied clinically and roentgenologically for 11 years, from 1937 to 1948. The calcium deposits developed in the subcutaneous tissues and in the deeper intermuscular fascial planes. The process started when the patient was 10 years of age and was first demonstrated as deposits of calcium in the right upper arm and shoulder, and in the left leg about the knee joint. Later, the condition spread to neighboring regions and the deeper fascial planes, and ultimately it began to involve also the right leg and the left upper arm. During all this time the widespread calcification process gave the impression of impermanence and instability, new deposits were constantly appearing and the older foci tended to fragment and reabsorb or discharge by way of ulceration through the skin. The progress was inconstant, irregularly advancing, and resting or regressing.

Histologic examination showed the true nature of the process to be the deposition of calcareous salts with hyalinization and ultimate destruction of the neighboring connective tissues. There was no evidence of a tendency toward either cartilage or fascial bone development. Nevertheless, chemical examination of the deposits exhibited about the normal proportions for the various calcium salts as have been determined for normal bone, and the metabolism of the calcium salts in the blood never showed any notable variation from the normal.

The diagnosis of interstitial calcinosis seems indicated, however, the characteristic of both the processes known in the literature as universal calcinosis and localized calcinosis seemed inextricably mixed together in this case and therefore no differentiation was attempted.

Since considerable involvement of the blood vessels leading to the involved areas was uncovered, it is thought that, in addition to the basic postulation of a congenital mesenchymal inferiority, a vascular factor should perhaps be included as a factor leading to this condition.

JOHN W. BRENNAN, M.D.

Hodgkin's Disease: A Histopathologic and Clinical Classification with Radiotherapeutic Response

PHILIP T. SAHYOUN and STUART J. EISENBERG *Am J Roentl*, 1949, 61, 369

A classification of Hodgkin's disease (exclusive of Hodgkin's sarcoma) based on histopathologic criteria is presented, and a correlation is made of the histologic picture, clinical course, and prognosis of this condition.

The first classification is the compactly cellular type, progressing slowly and with a maximum life expectancy range of 48 to 160 months. Histologically, there is proliferation mostly of the lymphoid and reticuloendothelial cells with the formation of Sternberg-Reed cells, and with few eosinophils and

plasma cells. Fibrosis and necrosis are not marked. Of 11 such cases presented, 7 were adequately followed up, and 5 of these showed a response to irradiation therapy and a clinical course consistent with the histopathologic expectations.

The second classification is the fibrogranulomatous type, progressing moderately and with a maximum life expectancy of 20 to 60 months. The typical histologic picture of Hodgkin's granuloma is found with marked cellular pleomorphism and abundant Sternberg-Reed cells, eosinophils, and plasma cells. There is hyperplasia of the reticuloendothelial cells and a tendency toward fibrosis and necrosis. Six cases were presented, and all were adequately followed up, they showed a response to radiotherapy and a clinical course consistent with their histologic type.

The third classification is the loosely cellular type, progressing rapidly, and with a range of maximum life expectancy of from 12 to 20 months. Histologically, there is complete destruction of the lymph node architecture and replacement by sheets of loose reticuloendothelial cells. Mitotic figures are abundant. The Sternberg-Reed cells are immature and the capsule and blood vessels may be invaded. Of 7 cases of Hodgkin's disease reported, 6 followed the expected course.

A brief review of the literature regarding the various opinions as to the cause and the histologic classification of Hodgkin's disease is presented. There is a general agreement of most authors regarding the classification of the types of cellular changes seen in this disease. The authors' classification, likewise, is comparable to those most generally accepted, and is based on a study of 24 cases which were followed up in an attempt to confirm the impressions of a correlation of the histologic classifications and prognostic criteria, previously gained during a number of years of study and observation.

DOUGLAS B. NAGLE, M.D.

The Hematological Effects of Ionizing Radiations

LEON O. JACOBSON, EDNA K. MARES, and EGON LORENZ *Radiology*, 1949, 52, 371

X-rays, gamma rays, fast neutrons, and slow neutrons are the principal forms of irradiation which affect the body, especially the hemopoietic system.

Acute whole body exposures (physical factors of 200 kilovolts, 15 milliamperes, 0.5 mm. copper, plus 1 mm. aluminum filter, high value layer 0.98 mm. copper) in rabbits, mice, and other animals revealed that with a dose of 25 roentgens there was a reduction in lymphocytes in the peripheral blood, returning to normal within 24 to 48 hours, with a dose above 100 roentgens the reduction of lymphocytes occurs within 3 hours, the maximum reduction within 24 to 48 hours. With a dose of 300 roentgens recovery requires 60 days. Monocytes follow the same pattern as lymphocytes, but return to normal in 4 to 6 days. Heterophil motility is observed following a

dose of 200 roentgens or more. The platelet count is reduced after a dose of 500 to 800 roentgens, recovery taking from 1 to 2 weeks. Anemia is present in dosages above 800 roentgens, with recovery within 20 days. The reticulocyte count is reduced from a normal of 3 to 5 per cent to less than 0.1 per cent within 72 hours.

Bleeding time is prolonged due to an increase in heparinlike substance in the circulation. The heparinlike state may be reversed by the administration of toluidine blue, protamines, and some thionin dyes. The hyperheparinemia may also be caused by nitrogen mustard.

Irradiation had no tendency to produce further anemia in animals with artificial anemia nor did it interfere with the recovery. This may have been due to a delayed response to previously stimulated erythropoietic tissue, as the actively dividing cells are less sensitive to irradiation.

The effect of fast neutrons on the peripheral blood in rabbits was similar to that caused by roentgen rays. Animal studies were also made of the hematological effect of chronic whole body exposure. Macrocytic anemia was also present.

The effects of prolonged whole body irradiation in human beings were similar to those found in animal experiments, the hemopoietic system was sensitive, with leukopenia and lymphopenia, and macrocytic anemia was present. Spontaneous recovery occurred, but the time factor was a variable one.

Morphological changes in the peripheral blood cells were described. They occurred between the tenth and twenty-fifth day.

Plutonium, an alpha emitter, produced anemia when the dose was above 0.0063 microcurie per gram of weight. The effect of radium was almost like that of plutonium, a dose of 0.02 to 0.03 micrograms being necessary to produce anemia. Yttrium, a beta emitter, produced a temporary leukopenia with doses of 0.1 to 0.3 microcuries. Sodium, a beta and gamma emitter, produced severe anemia in all animals receiving more than 12 microcuries. Barium and lanthanum, a beta and gamma emitter, produced anemia when given in 1.9 microcurie dosage, and death occurred when a dose of 17 microcuries was given. The minimal dose of strontium (a beta emitter) necessary to produce anemia has not been determined. Small doses of radiation do not stimulate cellular activity and multiplication.

A study of the personnel working on the plutonium project showed only a few instances in which peripheral blood changes could be attributed to irradiation. Inaccuracy of methods and individual variation made it difficult to interpret the findings. All groups received less than 0.1 roentgen per day. Further studies will have to be carried out on the biological action of ionizing radiation before definite conclusions can be drawn as to the possible damage that may occur with the use of such agents.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Metabolic Studies on Protein-Depleted Patients Receiving a Large Part of Their Nitrogen Intake from Human Serum Albumin Administered Intravenously CHRISTINE WATERHOUSE, SAMUEL H BASSETT, and JACOB W HOLLER. *J Clin Invest*, 1949, 28 245

The problem of protein depletion is urgent in the chronically ill patient who is unable to ingest adequate caloric or protein intake. Furthermore, the retention of nitrogen can be expected only when a certain critical caloric intake supplement has been made available in the form of carbohydrate and fat.

Protein hydrolysates and synthetic amino acid preparations may be poor sources of nitrogen because they are rapidly deaminated and excreted in urine. Also, they may give rise to vomiting and other reactions. Whipple and his co-workers believe that parenteral plasma protein can supply maintenance requirements. Plasma, especially when derived from large pools, may carry serum jaundice and its relatively high content of sodium is also a source of difficulty to the patient who has a tendency to collect edema.

Purified human serum albumin such as has become available through the Red Cross has the following advantages: a low content of sodium, general freedom from reactions, and freedom from viral jaundice. Its disadvantage is that it is deficient in both tryptophane and isoleucine.

Eckhardt and others concluded that albumin could maintain nitrogen equilibrium in man orally or intravenously and that supplements of tryptophane or isoleucine were unnecessary.

In order to further test the current theories, a series of experiments were set up. Subjects were chosen who were in need of protein but who were not acutely ill. The caloric intake was kept at as high a level as the patient would tolerate. None of the diets were protein-free, but (except in one instance) the amount of diet protein was too low to maintain nitrogen balance. Four subjects were studied. Each received a daily dose of 60 gm of concentrated sodium-free albumin for 10 or more days, preceded by a control period.

Results are discussed under headings of nitrogen balance, proteinuria, body weight, plasma protein and plasma volume, and calcium and phosphorus balances. Wherever possible, the data is exhibited in the form of graphs. The clinical course of each of the patients, and individual variations, are noted. In one instance a patient convalescent from rheumatic fever developed massive proteinuria but without evidence of impaired renal function. All 4 patients gained weight. The major factor was thought to be an expansion of the extracellular fluid. The

portion of albumin nitrogen apparently retained as protoplasm was inadequate to account for the weight gain. One patient, a woman with probable generalized vascular disease, retained water with resultant peripheral edema, hydrothorax, and pericardial effusion.

The variations in clinical results are discussed at length and an excellent bibliography of a related subject matter is appended.

KENNETH SHERMAN, M D

The Value of Implantation of Hypophyseal Tissue in the Treatment of Hypophyseal Insufficiency AXEL WESTMAN. *Acta med scand*, 1949, 133 171

The author discusses the value of implantation of pituitary tissue in the treatment of diseases which are more or less attributable to hypophyseal insufficiency.

The pituitary glands of recently slaughtered (not too young) calves were used. A small incision was made through the skin and a small pocket was subcutaneously prepared by blunt dissection, the glandular tissue was minced to a semisolid mass and instilled through the artificial hole into this pocket. In women, the labia majora forms a suitable bed for the implant because of the rich vascularization and favorable conditions in this area for resorption. In men, an area within the pectoral or gluteal regions was selected for implantation of the glandular tissue. In some cases suppuration and expulsion of the tissue occurred a few days after it had been implanted. It was found that this had no practical importance.

In menstrual disturbances it was found that previous treatments with estrone and thyroid had been unsuccessful in all of the cases observed. In addition, a large number of the patients were treated with serum or chorion gonadotropic hormone (antex, physex) which was also ineffective. Hence, the patients of this group were, from a therapeutic point of view, a selection of difficult cases. There were 36 cases of primary amenorrhea, in 3 of which the treatment was effective. There were 111 cases of secondary amenorrhea, in 32 of which the patients benefited from the treatment, and 5 patients became pregnant. There were 80 cases of hypo-oligomenorrhea, in 22 of which the treatment brought relief, 7 patients became pregnant.

In the 2 cases of adiposogenital dystrophy associated with cryptorchidism here presented, the treatment was effective.

Ten cases of alopecia totalis were studied, in 2 of them good results were obtained.

Five patients with alopecia areata were treated, in 1 of them treatment was successful.

Two cases of diabetes insipidus were studied, in these the treatment produced only a temporary effect.

In several cases of ovarian disorders the patients manifested also symptoms of other endocrine disorders, viz, adiposity, marasmus, and delay in stature growth. In a fairly large number the condition improved in connection with the establishment of the menstrual cycle. (The establishment of a normal cycle was verified by endometrial biopsies.)

With the implantation of pituitary tissue several hypophyseal hormones are administered to the patient. This is most important therapeutically, because in a large number of cases in which this treatment is indicated, the existing abnormality is attributable to pluriglandular insufficiency. This might explain why treatment by implantation of pituitary tissue is often more effective than the common hormone therapies.

The theory that the cells of the hypophyseal implant survive is not tenable. "Transplantation" of the pituitary body, therefore, is a misnomer and the procedure should be termed "implantation" of pituitary tissue.

Structure of the Liver in Fatal Burns JOSEPH GILLMAN and THEODORE GILLMAN. *South Afr J M Sc*, 1948, 13, 169

Examination of the livers of 38 patients dying from burns within from 1 hour up to 36 days after the accident disclosed three main types of reaction, namely, loss of stainability of the liver cells, fatty changes, and atrophy of cells in the central zone of the lobule. Patients dying within 13 hours of receiving the burn did not show very marked hepatic changes. In early deaths, the most striking changes in some livers were round cell and eosinophil and neutrophil accumulations in the portal tracts. Loss of stainability was seen mainly in the livers of patients dying within 9 hours and between 36 and 48 hours. This reaction was confined mainly to the region around the central vein. The granular cytoplasm occasionally contained a fat-free vacuole. Fat, in the form of small and medium sized droplets, could appear as early as 18 hours but was more consistently observed between 36 and 72 hours after

injury. The distribution was at first mainly around the central vein. At 96 hours fat was inconstantly present, but at 120 hours the fat was distributed also around the portal tracts, which is a feature of the livers of patients dying after the tenth day. From an analysis of the time sequence of the fatty changes it was suggested that the development of a very fatty liver requires at least 8 days. Atrophy of the liver cells around the central vein becomes manifest first in a liver at 36 hours after burns. Frank necrosis, such as has been described by others, was not observed in this series of cases. The authors suggest that extensive necrosis may have been intensified by lactic acid treatment, which was not used in any of their cases.

The highest death rate occurred within the first 24 hours, the next highest between 24 and 72 hours. Since there is scarcely any morphologic reaction in the liver under 18 to 36 hours, it is clear that no gross morphologic change in the liver can be correlated with the deaths within this period of time. Judging from the extent of the visible changes in the liver, it appears that at least within the first 120 hours death occurs mainly as a consequence of profound metabolic disorders and not because of any visible disorganization of liver structure.

JOHN L. LINDQUIST, M.D.

Basal Cell Carcinoma SIR CECIL WAKELEY and PETER CHILDS. *Brit M J*, 1949, 1, 737

A brief summary is presented of 27 cases of basal cell carcinoma (rodent ulcers) occurring in sites other than the face and scalp where, during the same period, 210 of such lesions were observed. All occurred in the older age group. The youngest patient was 47 years of age. Males predominated by the ratio of 25 to 2. The lesions in these cases were single, mobile, and presented no regional involvement of the lymph nodes.

The authors recommend surgical excision of all rodent ulcers in preference to irradiation because of its specificity, curability, lower incidence of post-operative complications, and economic practicability.

Hospital Expenses Reduced by Needle Standardization

Substantial savings are made when surgical staff personnel standardizes on needles as suggested in the above chart. The eyeless needles are always ready and are easier to use. No unthreading. Operating time reduced.

The hospital reduces its inventory and investment. Nurse time is saved by eliminating preparation and sterilization. There is no need to scrub, polish or sharpen the needles.

OXYGEN THERAPY

Simplified

OHIO'S extensive line of oxygen equipment simplifies oxygen therapy by providing the latest developments in apparatus which employs the most recent techniques • Included are oxygen tents cooled either by ice or by electric refrigeration, inhalator masks, oropharyngeal catheter outfits, plastic hoods, and even bedside units of simpler construction The complete line meets every requirement of hospital or clinic • A particularly valuable nation wide service provided by "Ohio" is the day and night oxygen delivery and equipment rental available from Ohio branch sales offices in 30 principal cities • The catalog, "Ohio Oxygen Administering Apparatus," gives complete details of both equipment and rental service Write for a copy Or for immediate information call our nearest branch sales office

THE EFFICACY AND THE SAFETY OF THE INTRAMUSCULAR ADMINISTRATION OF BACITRACIN IN VARIOUS TYPES OF SURGICAL AND CERTAIN MEDICAL INFECTIONS

With an Analysis of 270 Cases

FRANK L. MELENEY, M D, F A C S, New York, New York, ALFRED B. LONGACRE, M D, F A C S, New Orleans, Louisiana, WILLIAM A. ALTEMEIER, M D, F A C S, Cincinnati, Ohio, EDWARD H. REISNER, Jr., M D, New York, New York, Major EDWIN J. PULASKI, M C, U S A, F A C S, Fort Sam Houston, Texas, and HAROLD A. ZINTEL, M D, F A C S, Philadelphia, Pennsylvania

THE first report on the systemic administration of bacitracin was presented to the American Surgical Association at Quebec in May of 1948 and appeared in October of 1948 in *Annals of Surgery*. The report covered 105 cases of various types of infection, chiefly surgical (5). These patients for the most part received the commercial product manufactured by the company herein referred to as company A, and it was produced by the *surface growth* of the organism.

The number has now reached 270 cases and another report seems to be in order, because

Part of the work was done under a grant from the Research and Development Board of the Office of the Surgeon General of the Army and part under a grant from the United States Public Health Service.

Dr. Meloney from Laboratory for Bacteriological Research, Department of Surgery, College of Physicians and Surgeons and the Presbyterian Hospital, New York; Dr. Longacre from Department of Surgery, Louisiana State University and the Charity Hospital, New Orleans; Dr. Altemeier from the Department of Surgery, University of Cincinnati and the Cincinnati General Hospital, Cincinnati; Dr. Reisner Jr. from the Department of Medicine, New York University Post Graduate Medical School and Bellevue Hospital, New York; Major Pulaski from Surgical Research Unit, Brooke General Hospital, Fort Sam Houston; and Dr. Zintel from Department of Surgery, University of Pennsylvania and the University Hospital, Philadelphia.

we have had further experience with this potent antibiotic produced by a different method, namely by the *deep tank* growth of the organism, manufactured by the company herein referred to as Company B. This experience has covered the period since January of 1948, when temporary specifications were set up by the Food and Drug Administration for the purpose of insuring the efficacy and safety of the antibiotic. The data herewith reported were obtained by means of a co-ordinated study of cases treated by several observers in different parts of the country, planned in such a way as to minimize the personal equation in the appraisal of this drug. The uniformity of the study was insured by the careful preparation and adoption of a summary sheet, which was designed to bring out all of the essential features of the individual cases, particularly with regard to the diagnosis, the duration of the illness, the previous antibacterial agents used to control the infection, the status of the blood, the function of the kidneys before, during, and after treatment, the daily dosage, the interval and the

of manufacture. But the manufacturers gradually eliminated many of these impurities and finally gave us a highly soluble, faintly yellowish powder in lyophilized form, which could be dissolved in water or saline and then injected subcutaneously, intramuscularly, or intravenously into animals. These preparations permitted certain pharmacologic studies, which were carried out and reported by Dr John Scudi and his associates (11, 12, 13). These studies clearly demonstrated that the drug could be well tolerated by laboratory animals in doses which were effective in the control of infection produced experimentally by susceptible organisms, such as the hemolytic streptococcus and the clostridia of gas gangrene. The only evidence of injury to the body tissues (and this was obtained only by large doses) was in the lower nephron of the kidneys of mice. There was no evidence of injury even in these areas in any other animal in the doses which were employed, except slight changes in the kidneys of monkeys. Dogs, rabbits, rats, and cats seemed to be entirely free from even this evidence of toxicity. It was also found that the drug could be tolerated in very much larger doses, if given intramuscularly and subcutaneously than if it were given intraperitoneally or intravenously. Total doses, divided and administered every 4, 6, or 8 hours over a period of one or more days, gave very much less evidence of kidney irritation than if given as a single dose.

On the basis of this experience we began cautiously to administer bacitracin to human beings, first to members of the laboratory staff, and then to patients who were the victims of infection. These patients were studied carefully to demonstrate any evidence of injury to the kidneys or other organs. It was soon demonstrated that albumin appeared in the urine of the majority of these patients on the third, fourth or fifth day of treatment, but that it disappeared with the continuation of treatment. Along with the albumin, but less frequently, granular casts would appear and an increase in the white cells and the epithelial cells. However, these evidences of kidney irritation were always transient and disappeared from the urine either during the course of treatment or as soon as treatment was

stopped. In only one case did it interfere with the administration of the drug. During this period, those who were using bacitracin systemically did so with increasing confidence in its safety and freedom from significant toxicity.

At this time Dr Harry Eagle, finding the spirochetes of syphilis particularly susceptible to bacitracin, began his study of human syphilis with various doses of intramuscularly administered bacitracin. He found that there was remarkable synergistic action between bacitracin and penicillin both *in vitro* and *in vivo* in the cure of experimental rabbit syphilis (2). He therefore treated two series of patients, one with bacitracin alone and the other with bacitracin and penicillin together. He observed albumin in the urine of treated cases, but it did not seem to be of clinical significance (1).

After using several lots of the Company A (surface growth process) product with steadily increasing confidence, it was found that with a certain new lot one patient became upset with persistent nausea and vomiting. This occurred at a time when the Company A laboratories were trying to step up their production, and it was thought that something had crept into the manufacture, carrying with it some toxic factor. No further patients were treated with this lot and with subsequent lots these toxic manifestations were absent. We became bold enough, thereafter, to increase the dosage gradually to 30,000 to 50,000 units every 6 hours in order to have a wider therapeutic margin.

A patient with malignant endocarditis, which had not come under control with 20 million units of penicillin or 8 grams of streptomycin a day, was given 50,000 units of bacitracin every 6 hours and later the same dose every 4 hours without evidence of toxicity. There was improvement, but our supply of bacitracin became exhausted and treatment was stopped. The patient then became much worse and several days later when more bacitracin became available, he was moribund. He was given 100,000 units every 4 hours, but it did not save him. At autopsy there was some evidence of tubular injury, possibly due in part to bacitracin, but Professor H. P. Smith of the Department of Pathology gave his opinion that no pathological changes were found which could not be accounted for by the disease itself.

In the meanwhile 13 other pharmaceutical houses undertook the preparation of bacitracin

and all ran into difficulties. Some of these firms were determined to find a way to produce the antibiotic by deep growth in large tanks. Company B was in the van in this race, but ran into a number of difficulties before solving the problem of deep tank production. When the Company A laboratories realized that if a deep tank method were found, surface growth could not compete with it economically, they arranged with the Company B to turn over to them all of their experience and their whole stock of bacitracin and agreed to discontinue production. Thereafter the only material made by the surface growth process was distributed to the study units under the Company B label, although the original Company A lot numbers were retained.

The units which had been set up early in the program had on their hands a stock of the Company A material, which they continued to use on their patients. These included the units in Presbyterian Hospital, New York, in Bellevue Hospital, New York, in Charity Hospital in New Orleans, and in the Cincinnati General Hospital. Using the Company A product, these units generally started with 20,000 units every 6 hours for an adult. If there was no response in 24 to 48 hours, the dose was not infrequently increased to 30,000, 40,000, or 50,000 units. Therefore, when the deep tank product became available, the same doses were employed.

The two new units set up in the University Hospital at the University of Pennsylvania in Philadelphia and in the Brooke General Hospital at Fort Sam Houston had little experience with the Company A product and their first clinical trials were carried out with the early deep tank product of Company B. In the Brooke General Hospital the daily doses were generally limited to 80,000 units. Over a period of 6 months about 20 patients were treated. About half of the patients received 10,000 units and the other half, 20,000 units every 6 hours. In the Philadelphia unit their first experience was with cases of endocarditis, which had failed to respond to penicillin and therefore it seemed wise to give as large a dose as could be tolerated. Most of their patients therefore received 50,000 units every 6 hours for a total of 200,000 units daily.

It was soon evident that the reports from these two units were disturbing, because not only did albumin appear in the urine 2 to 3 days after bacitracin treatment was started, but there was frequently a shower of cellular elements from the kidney. Furthermore, the patients developed a lethargy which persisted for some time and along with it a rise in the retained nitrogen, as indicated either by the tests for the serum urea nitrogen or nonprotein nitrogen. At the same time there was frequently a fall in the filtration rate of phenol sulfonphthalein and a lowering of specific gravity. Such findings could not always be correlated with the dosage. The difference often seemed to be due to individual idiosyncrasy rather than to the amount of the material administered.

A month or so later the other units gradually used up their supply of Company A material and began to treat patients with the early product of Company B. One by one all of the units found that they were running into similar difficulties, which they had not experienced with the Company A material.

With his knowledge of renal physiology as a background, a study was carried out at the University Hospital in Philadelphia by Dr Alexander Michie, to determine the effect on renal function of the big doses used by the Philadelphia unit. Figures were obtained in the cases of 6 patients treated with two different lots of the early Company B product in doses of 50,000 units every 6 hours for a period of from 3 to 15 days. It was found that there was an appreciable diminution of glomerular and tubular filtration as well as renal blood flow. These results were not uniform. There was wide variation in different individuals, but there was a definite average decrease in all of these functions. At the same time albumin and an increase in the cellular elements appeared in the urine (7).

These clinical and laboratory experiences made it obvious that it would be necessary to study the problem of toxicity with renewed zeal. All of the records were therefore gathered together and the case histories were studied from the point of view of the lot numbers used and the dosage. These data were correlated with the laboratory and clinical

evidence of kidney irritation. The results of this study are shown in Tables I and II. At the same time a series of experiments were carried out in the laboratory in order to compare the Company A material produced by surface growth with the product of Company B grown in the deep tanks. Six lots from each firm, which had been used clinically, were selected and saline solutions of the antibiotic were injected subcutaneously into mice in doses ranging from 250 to 1,000 units. Four hundred and eighty-four mice were used in this study. With each lot the death rate was noted and after a period of several days the surviving mice were subjected to autopsy and notes were made with regard to the evidence of gross renal pathology.

When all of the clinical and laboratory data were gathered together, it was obvious that the early product of Company B was definitely more toxic than the Company A material. Furthermore, these data indicated that different lots of Company B material varied considerably from one another in their toxicity. This variation between different lots was confirmed by the results of the toxicity tests carried out in the laboratory of Dr Henry Welch of the Food and Drug Administration.

No LD₅₀ tests were carried out by the Food and Drug Administration with the Company A surface growth product, because specifications were not set up until January of 1948, after Company A had ceased its production and had turned over all of its supply to Company B. At that time it was felt that an LD₅₀ of 200 units for a 20 gram mouse would provide an adequate margin of safety. The early product made by the deep tank method met this specification, but the Food and Drug Administration tests revealed that different lots varied all the way from 224 to 500 units, while the assay of potency per milligram of material remained fairly constant (see Table II). Furthermore, it was found that the Food and Drug Administration tests could be correlated with the laboratory and clinical data mentioned above. It was then clear that Major Pulaski, Dr Zintel, and Dr Michie had been making their observations for the most part with relatively toxic lots, while Dr

 §Albumin 4 plus moderate to many granular casts, white cells epithelial cells and few to moderate red cells or nausea and vomiting or significant rise in retained nitrogen, or considered advisable to stop treatment for any other reason.

Longacre and Dr Reisner had been working with lots of low toxicity.

It was then agreed that further systemic use of the antibiotic by all of the units should be limited to material which could meet the specification of LD₅₀ of 500 for a 20 gram mouse. Company B had demonstrated that it could meet this specification. It was further agreed that for the time being the initial dose should be approximately 200 units per kilogram of body weight. This dose might be doubled or tripled if occasion warranted in the judgment of the observer. This plan has been followed since July of 1948, and the favorable results in the last hundred cases have amply justified this program.

In order to be certain that the low incidence of nephrotoxic responses in the patients receiving the bacitracin with the LD₅₀ of 500 was not simply a question of low dosage, 6 patients during this period were given material from two lots which fell short of this specification. Table II reveals that 3 of 4 patients receiving lot No 480512 in the same dosage gave disturbing symptoms and signs of toxicity. One of these (Case 5) had received the Company A material the year before for over a month in a daily dose 50 per cent larger without evidence of toxicity. The toxic symptoms and signs all disappeared in the others when the treatment was changed to the lots meeting the specification. Virtually the same results were obtained in the 2 patients treated with lot No 480520. These observations with regard to dosage are amply confirmed by the fact that the toxic effects observed by Major Pulaski were all obtained with doses of the

antibiotic not exceeding 80,000 units per day with lots of relatively high toxicity.

This rather long dissertation on the problem of toxicity seems necessary in order to help the reader of this report to understand the difficulties which have been met and largely overcome during the course of this study. The first phase was a period of calm, the second a storm of uncertainty, and the third phase a period of increasing confidence in the efficacy and safety of this new antibiotic.

Further efforts are being made to reduce the toxic factor still more or to eliminate it entirely from the active principle. If by the present methods of production the manufacturers can meet this specification of LD₅₀/500 we believe that bacitracin should be made available for more extended use in hospital. Only those patients should be treated who can be watched carefully and in whom urinalysis can be performed daily and tests for retained

MELENEY ET AL ADMINISTRATION OF BACITRACIN IN INFECTIONS

nitrogen made once or twice a week. The first clinical sign of toxicity is lack of appetite and if this increases, nausea may occur and in still more toxic cases, vomiting. The more subtle changes can be determined by the microscopic examination of the urine and the test for the nonprotein nitrogen retained in the blood. If any patient needs bacitracin treatment, an albuminuria of 1 plus to 3 plus or an increase of 50 to 100 per cent in the non protein nitrogen do not constitute a contraindication to continued use of the drug, and it should not be stopped unless the symptoms become really alarming, because the toxic factor is far outweighed by the therapeutic value of bacitracin and one can be sure that these changes are reversible and that the kidney function will be restored to normal sooner or later after cessation of treatment. This fact was repeatedly demonstrated in every case which was brought back for checkup. Many patients with infection show some evidence of kidney irritation before bacitracin is started, either albumin in the urine, casts, an increased number of cells, or a high non-protein nitrogen. This is not a contraindication to the use of bacitracin, because an analysis of our data shows no correlation between toxic manifestations and previous evidence of kidney damage. These signs do not usually increase during treatment, a fact suggesting that the toxic reaction is more a question of individual idiosyncrasy rather than the result of damage already present in the kidney.

ANALYSIS OF RESULTS

Completed summary sheets for 270 cases from the different units have been turned in to the central office. These include 25 cases of pneumonia which Dr. Reisner has carefully studied and has reported (10). Suffice it to say here that his experience clearly indicates that bacitracin is effective in curing pneumococcus pneumonia, that most of the organisms producing this disease are susceptible to bacitracin, and that the clinical symptoms disappear promptly following its use. Favorable results have been obtained by doses as low as 10,000 or 15,000 units every 6 hours, but doses of 30,000 units every 6 to 8 hours for a period of 5 to 7 days are advocated in cases with pneu-

mococcus bacteremia. Reisner recommends the determination of the sensitivity of the invading organism and giving doses large enough to produce blood levels ten times this sensitivity. In some of his cases he gave as high as 99,000 units every 6 hours, and with the lots which he employed, the evidence of nephrotoxicity was minimal. He considers that bacitracin is only slightly more toxic than streptomycin (3). None of his patients showed any permanent or serious damage to the kidneys. He recommends the use of bacitracin in cases of pneumonia where there is a sensitive organism which does not respond to penicillin. He found a high level of bacitracin in the pleural exudate and recommends its intrapleural local instillation in cases in which organisms are present in the pleural fluid.

Of the remaining cases, 7 patients have received the drug prophylactically. In none of these did infection develop, but little can be said of its prophylactic use at this time. The other 238 cases represent 76 different clinical groups. They are listed in Table IIIa and the results obtained are shown in adjacent columns. Forty-five of these are called miscellaneous because there was only 1 case in each diagnostic classification. Thirty-two had 2 cases under each of 16 different diagnoses. All the other clinical entities had 3 or more, the largest group being classified as cellulitis, which is a diffuse inflammation of the skin and subcutaneous tissues with very little evidence of localization of the process in the early stages of the lesion.

If we consider the "excellent" and "good" results as favorable and the "questionable" and "no effect" as unfavorable, we find that in this whole group about two-thirds gave a favorable response to bacitracin. There are about twice as many cases in the "good" category as in the "excellent."

Certain of the groups are worthy of special note. For example, it is seen that in the cases of cellulitis, there are more excellent responses than good. This is also true of synergistic gangrene and staphylococcal meningitis. Furthermore, in infected accidental wounds and in carbuncles there was a better than average percentage of favorable results. Particularly poor results were obtained in endocarditis, all

kinds and conditions of infections, including those in which the organism is not known or cannot be determined It has also been tried in many cases which are probably not infections at all and which have been included in the "no effect" column Furthermore, no patient was refused treatment when the call was made for bacitracin Even though he was moribund, it was given to the patient in the hope that it might turn the tide Some of the patients with infections thought to be hopeless nevertheless surprised everyone and recovered

Tables IIIb and IIIc show that about one half of the patients were treated solely with systemic bacitracin, while the other half received the drug both locally and systemically The results in the latter (75.6 per cent) seem to be much better than in the former (56.4 per cent), but it is obvious that these two

Series are not comparable because in the former group the infections were more serious, the inflammation was more diffuse and often was not sufficiently localized to permit local treatment. Many of the latter group had the benefit of surgical drainage and the removal of dead tissue or slough and the drug could be applied to the area of infection in a concentration far above that which could be reached by systemic injection alone. Nevertheless, the favorable response in cases of cellulitis, syner-

gistic gangrene, and acute osteomyelitis clearly demonstrates the value of a drug coming through the blood stream to the area of infection and limiting its spread by infiltration into the periphery of the lesion. A study of these two subsidiary tables clearly reveals, however, that many of the patients treated with systemic bacitracin alone could have had the advantage of combined local treatment, and the figures suggest that the results for this group might have been improved thereby.

Previous treatment unknown	11	3	3	4	1

About three-fifths of the 270 patients had had previous treatment and were sent for bacitracin treatment because these methods had failed. The authors recognize fully that the percentage (56 per cent) of these failures is far higher than for all patients with infections coming to a doctor's office or to an out-patient clinic. These were all seriously ill patients requiring hospitalization and many of them had been ill for a long time. The units set up for the appraisal of bacitracin were known to have a new method of treatment

available. Therefore patients not responding to other forms of treatment naturally gravitated toward these centers or were referred there by their local doctors. They had been given the best treatment that their doctors knew how to give for their particular trouble and yet they had failed to respond to the initial treatment or to a combination of treatments. Nevertheless there was a favorable response to bacitracin in 55.6 per cent. This breakdown of the cases is shown in Table IV. The great majority of these patients would almost certainly have gone on with their infection to prolonged, temporary, or permanent disability or death. Therefore it seems fair to call these "salvaged cases" for whose recovery bacitracin should be given full credit. With regard to previous treatment, 126 had received either penicillin alone or penicillin in combination with other drugs. The three largest groups were "penicillin only," in which there were 37, "penicillin and some sulfonamide," 31, "penicillin, streptomycin and some sulfonamide," 28. Of the 96 cases in these three main categories of previous penicillin treatment, there were 23 which gave a brilliant response to bacitracin, and in 32 it was called "good," a total favorable response of 57 per cent.

Of the 119 cases that had had no previous systemic treatment the favorable results were 78.1 per cent. This difference can be explained largely on the basis of earlier treatment in the latter group.

This would seem to indicate that if the primary treatment had been bacitracin, the results in the first group would have been better. It is obvious that the cases of patients who had had previous treatment were of longer standing than of those who had none. The infection had gained a deeper foothold and the organisms were often resistant to penicillin and the other antibacterial agents which had been employed. Thus the chances of success with bacitracin in the first group were greatly prejudiced. When these cases are studied from the point of view of the duration of the illness before treatment, it is seen in Table V that in the patients who had failed to respond to previous treatments, almost one-half of them (43 per cent) had chronic infections,

that is, their symptoms had lasted for over a month, whereas in the "no previous treatment" group the percentage of chronic cases was only 13 per cent. Thus by the time the first group received treatment, the organisms had not only become more firmly entrenched, but there were unquestionably factors of malnutrition and anemia with necrosis of tissue, all of which interfered with a successful outcome. In both of these groups the table clearly indicates that in general the earlier that treatment was administered, the better were the results obtained. All of those in both groups with symptoms lasting for only 24 hours responded favorably, but unfavorable responses began to appear as the duration of illness increased. In patients with symptoms lasting for 7 days or less in whom previous treatment had failed, bacitracin was successful

in 66 per cent. In the cases of 7 days' duration or less with no previous treatment, the favorable response to bacitracin was 81 per cent. Nevertheless, it is seen that in 5 patients with chronic conditions that had been going on for over a month and which had failed to respond to other agents, the responses to the treatment with bacitracin were brilliant.

In the majority of cases a careful and complete bacteriological analysis of the purulent exudate was made, but in a certain number of this was impossible. The largest group of those in which no culture was taken were cases of cellulitis, usually caused either by the hemolytic streptococcus or the Staphylococcus aureus. It is always difficult to obtain a culture, if there is no breakdown of tissue. Where there was an exudate, however, analysis was made and all of the organisms which were recovered were subjected to tests for susceptibility to bacitracin and penicillin and in many instances to streptomycin as well (see Tables VIa and b).

S—Susceptible R—Resistant

Very often a bacteriological laboratory will report the *predominant* organism in a given culture rather than give a complete list of all species present. Many laboratories make no anaerobic cultures. Thus many *significant* organisms are missed. In this series an effort was made to find all of the representative organisms and in doing so it was found that the majority of cases were infected with a mixture of organisms. This is particularly true of chronic cases. Only 88 of the 238 cases had organisms in pure culture, and unless the 43 cases from which no cultures were taken were in fact pure infections, which is unlikely, the remainder had mixed cultures, which totaled 107. The results clearly indicate that even with mixed cultures bacitracin is effective in controlling the infection. This is due to the fact that bacitracin has a very wide antibacterial spectrum and is not inhibited as is penicillin by the penicillinase producers, which are so frequently present in mixed infections. These include not only a large number of species of aerobic gram negative rods, but even among the staphylococci which are resistant, we find many which produce penicillinase. It is of interest to note that the coagulase positive staphylococci are the only

ones in which pure cultures approach closely in number the mixed cultures. Probably the strains of staphylococci for which the coagulase test was not done were for the most part pathogenic.

The low incidence of the hemolytic streptococci is a reflection of the secondary role which they play since the advent of the sulfonamides. It is not surprising that the aerobic gram negative rods are seldom present in pure cultures, as they are essentially saprophytes, but that this was true of the anaerobic and microaerophilic cocci was somewhat unexpected.

Of particular interest is a comparison of the cultures in their susceptibility to bacitracin and penicillin. Table VIIa shows that 122 species were susceptible to both, 104 were susceptible to bacitracin and resistant to penicillin, while only 11 were resistant to bacitracin and susceptible to penicillin. Thus it is seen that when there was a difference in susceptibility to these two antibiotics, the ratio was about 10 to 1 in favor of bacitracin. This ratio is twice as great in favor of bacitracin as appeared in a similar study 2 years ago (6). This would seem to indicate that as time goes on an increasing number of organisms are found to be resistant to penicillin and still are susceptible to bacitracin. Again it must be remembered that this is not the ratio one would meet with in cultures from a doctor's office practice or an ordinary clinic. It applies solely to this series, which contains a majority of cases which had failed to respond to previous treatment. In this series 92 strains were resistant to both bacitracin and penicillin, the great majority of these being aerobic gram negative bacilli. It is seen that the balance in favor of bacitracin is most striking with the coagulase positive staphylococci and the streptococci, both hemolytic and nonhemolytic, but it is true of every bacterial group. It must be remembered, of course, that a large portion of these patients had had penicillin. It is not known whether the organisms were originally susceptible and developed a resistance to penicillin or were originally resistant.

If this table showing bacterial susceptibility to bacitracin and penicillin is broken down so as to reveal the difference between the group

which had been previously treated with systemic penicillin and the group which had not, the ratio of bacitracin to penicillin in the first group is 35 to 1 (see Table VIIB), while in the latter group the ratio is less than 4 to 1 (see Table VIIC). This would seem to indicate clearly that many organisms had built up a resistance to penicillin in response to treatment with it. A comparison of the acute and chronic groups in this regard shows that there is no essential difference, so it is not a feature of the passage of time alone.

In the appraisal of any antibiotic, of greatest interest are the cases which respond promptly, dramatically, "brilliantly," "miraculously" and in which there is no doubt in anyone's mind that the drug has been a potent factor in the control of the infection. But perhaps from a scientific point of view of equal importance are those cases in which the effect of the drug is nil. Among the questionable cases there is room for argument as to whether the drug helped or not, but not among those in the column in which there was obviously no effect. There were 61 of these cases and an attempt has been made to analyze the reasons

for failure. In 8 of them the patient was moribund and perhaps they should not be included in the series, but the authors wish to point out that treatment with bacitracin was never refused in order to bolster statistics. It was sometimes given when it was obvious that any treatment was utterly hopeless. There were 11 cases in which the causative organism proved to be resistant to bacitracin. The 7 cases of endocarditis had all had prolonged and unsuccessful treatment with large doses of other antibacterial agents. Successful treatment of such cases will have to await the further purification of bacitracin. In 8 cases treatment with bacitracin was discontinued because of some evidence of nephrotoxicity, and in one it was stopped because the patient complained of the pain of injection. In some of the remaining cases it was obvious that the nature of the illness, the extent of the lesion, the degree of tissue necrosis and the inaccessibility of the infection to the drug seemed to explain the failure, while in the remainder the cause of failure was not apparent.

The following brief outlines of case histories will illustrate the results which were obtained

during the three phases of this study and will serve to emphasize what has been mentioned above, that during the first phase while we were using the surface growth material the evidences of nephrotoxicity were inconsequential. In the second phase, when we were using the earlier product made in the deep tanks, the nephrotoxicity was disturbing. In the last phase, while we were using the material which meets a Food and Drug Administration toxicity test of LD₅₀/500 units for a 20 gram mouse our confidence in its efficacy and safety has been largely restored.

CASES ILLUSTRATING THE RESULTS OBTAINED WITH "SURFACE GROWTH" BACITRACIN DURING THE FIRST PHASE OF THE STUDY

CASE 1 J. B., male, aged 43 years. Deep abscess of thigh. Series No. 1007.

Three weeks before admission this patient was taken ill with chills and fever and generalized aches and pains. Two days later a tender mass appeared in the upper inner area of the left thigh. He was given penicillin with temporary subsidence of the mass but then it recurred and did not respond to further treatment with penicillin. On admission to the hospital he was given 15,000 units of bacitracin every 6 hours with prompt improvement, subsidence of the mass, and freedom of movement without pain. However, the mass did not completely disappear. Improvement came to a standstill and temperature and blood count remained high. The mass was explored and found to be a deep abscess around the femoral vessels which yielded on culture a hemolytic streptococcus. The dose was increased to 30,000 units and the abscess cavity was irrigated daily with bacitracin solution containing 1,000 units per cubic centimeter. Exudation in the cavity decreased rapidly and on the fifth day of local treatment the wound was closed with sutures and it healed by primary union. The stitches were removed on the sixth day after suturing. Systemic bacitracin was stopped on the following day and he was allowed to walk around. Two days later he was on schedule to leave the hospital, but his temperature rose slightly and pain recurred in the thigh. He was put back to bed and systemic bacitracin again administered, 30,000 units every 6 hours with immediate improvement. Residual induration in the thigh, however, indicated aspiration, which yielded 25 cubic centimeters of pus. This was replaced by 2,500 units of bacitracin. Daily aspiration of pus and instillation of bacitracin caused a rapid subsidence of the process, and no treatment was needed after the fourth day. The patient has been followed over a period of 28 months, and there has been no evidence of recurrence of the process nor symptoms or signs of nephrotoxicity.

CASE 2 O. C., female, aged 46 years. Cellulitis of arm. Series No. 1005.

Four months before admission a hemorrhage in the right arm was followed by infection which was not controlled by incision. The cellulitis eventually spread to involve the whole arm. A second incision on the inner surface also failed. The circumference of the arm from elbow to chest was red and markedly swollen. Beside the incisions which had never healed spontaneous abscesses had developed. Culture revealed a hemolytic streptococcus susceptible to penicillin and bacitracin and a hemolytic *Staphylococcus aureus* resistant to penicillin but susceptible to bacitracin. With intramuscular 15,000 units of bacitracin every 6 hours the sinuses began to close after 48 hours. In 14 days healing had occurred and surgical treatment was obviated.

CASE 3 A. W., female, aged 32 years. Postoperative bacterial synergistic gangrene. Series No. 1013.

This was a typical case of this disease of 4 months' duration following a hysterectomy, which did not respond to penicillin, streptomycin, sulfadiazine and many forms of local treatment, including a total operation. The infection jumped over the incision and spread out into the flanks and down both thighs. Cultures showed a mixture of organisms, *pyococcus proteus* and a hemolytic *Staphylococcus aureus* susceptible to bacitracin but resistant to penicillin. The microaerophilic nonhemolytic streptococcus was not found, probably being masked by the *proteus* and *pyococcus*, which may have been responsible for the failure of penicillin to control the infection. In 48 hours, after receiving intramuscular bacitracin in a dosage of 20,000 units every 6 hours, the spread of the infection ceased and the gangrenous material had begun to separate spontaneously. The wound was completed in 72 hours and epithelium very rapidly spread over all the surface from remnants of the hair follicles and sweat glands. The proteus and pyococcus factors of the infection were controlled by the local application of 0.25 per cent parachlorophenol solution combined with bacitracin in a concentration of 500 units per cubic centimeter. Final epithelialization was favored by a 2 per cent oxyquinoline and 5 per cent scarlet red ointment. Healing was completed in 8 weeks without the necessity for excision or skin grafting.

CASE 4 N. A., male, aged 22 years. Infected operation wound with cellulitis of back. Series No. 1024.

A sebaceous cyst was removed from the lower posterior chest and within 12 hours a red hot infection developed which spread over all the back and left flank. He was very toxic and the infection did not respond to three doses of 500,000 units of penicillin in oil at 12 hour intervals with 50,000 units of bacitracin every 2 hours. The culture yielded a group A hemolytic streptococcus and a coagulase positive *Staphylococcus aureus* both sensitive to both penicillin and bacitracin. It has been observed before that if

combination may resist penicillin treatment even though the individual organisms in pure culture are susceptible. He was given 20,000 units of bacitracin every 6 hours. The toxicity promptly disappeared and within 12 hours his temperature fell to normal, the cellulitis melted away and the wound went on to rapid healing.

CASE 5 V H, male, aged 24 years. War wound with suppurative osteomyelitis of the stump of the femur. Series No 1023.

A Marine lieutenant had received a compound fracture of the femur, produced by a dum dum bullet at Iwo Jima. He was given penicillin and sulfadiazine, but developed an infection which failed to respond to surgical drainage and the further administration of antibacterial agents. He was transported to Pearl Harbor, then to San Francisco, and to Chelsea, Massachusetts. In each place there was a flare-up of infection, treated by multiple incisions for drainage. Finally, at Chelsea amputation was done to save the patient's life, but the stump became infected. A transfer to Philadelphia and further incisions and more drugs failed to control the infection. After 3 years, draining sinuses were still present at the end and on the lateral surface of the stump. Cultures revealed a *Staphylococcus aureus* susceptible to bacitracin but resistant to penicillin, and *Bacillus proteus*.

On admission the x-ray films showed residual foreign bodies and osteomyelitis of the stump. He was given intramuscular bacitracin in a dosage of 18,000 units every 6 hours. After 2 days the dose was increased to 33,000 units. On the third day he was operated upon. Most of the metal and all of the diseased bone were removed. Bacitracin was instilled locally into the bone cavity by means of plastic catheters. There were also two separate abscess cavities on the inner side of the thigh, which were drained through separate small counter-incisions and bacitracin was instilled into these cavities. The catheters were removed on the fourth day. The lateral wound granulated rapidly and on the seventeenth day the granulations were covered with pinch grafts. Healing was complete in a month. During this time the patient gave no evidence of renal toxicity from a daily dose of 120,000 units a day, except for a little albumin and a few casts lasting 3 days in the early days of the treatment (See Table VIII). This table is typical of cases treated in the "first phase" of the study. A year after the above treatment the pebbly area of skin was excised and a primary closure of the wound was successful with the aid of systemic bacitracin for 10 days.

CASE 6 J L, male, aged 27 years. Osteomyelitis of the radius following bone graft operation. Series No 1027.

This was an American infantry officer wounded in Germany by a rifle bullet through the left forearm, both thighs, and the scrotum. He was captured by the Germans and recaptured by the Russians. He was finally evacuated through Odessa. By that time

3-3				23		

This table shows that a daily dose of 120,000 units of the surface growth bacitracin for over a month was well tolerated and resulted in minimal and only transient evidence of kidney irritation. This was typical of all but 1 or 2 cases during the first phase of the study.

spt. Smallest possible trace st slight trace t, trace ht heavy trace.

all wounds had healed. He was sent to an American army hospital where because of the shortening of the radius, a bone graft was introduced. The wound healed without apparent infection, but a month later an abscess formed and came to the surface. It was surgically drained and a number of small sequestra were found and others came out later. The wound then healed slowly, but flared up again a week before admission to the hospital. X-ray films revealed osteomyelitis around the lower screws (see Fig 1). These screws and the infected bone around them

were removed. The cultures showed a *Staphylococcus aureus* susceptible to bacitracin but resistant to penicillin. He was given 20,000 units of bacitracin every 6 hours for 11 days and it was also instilled locally into the wound. This gradually filled with granulations and healed. During the course of treatment the patient had nausea and vomiting, but this did not interfere with treatment. There was albumin in the urine and a moderate transient rise in non-protein nitrogen.

CASE 7 E W, male, aged 24 years. Actinomycosis of hand. Series No 1016.

This patient developed an actinomycosis of the hand in a wound from a tooth injury. This steadily increased in size over a period of 11 months. *Actinomyces bovis* was cultured from the wound as well as *Staphylococcus aureus* susceptible to bacitracin but resistant to penicillin. He was put on intramuscular bacitracin in a dosage of 20,000 units every 6 hours for 3 days. On the third day the swelling began to subside. The dose was doubled, but because of some nausea and vomiting after 3 days it was reduced to the original dosage. After 10 days the patient insisted upon leaving the hospital because of certain home responsibilities and he did not come back for a month, at which time it was found that the swelling had increased. An x-ray examination revealed that the third metacarpal bone was involved in the process (see Fig 2). It was decided that the best chance for recovery would be an excision of the local lesion and a continuation of drug treatment. He was therefore given 22,000 units of bacitracin every 6 hours. The diseased tissue was removed. This included the third and fourth fingers and their corresponding metacarpal bones and a portion of the os magnum. The wound was closed primarily with a small plastic catheter placed in the web, through which bacitracin was instilled locally for 3 or 4 days. The catheter was then removed. The wound healed by primary intention and excellent function of the hand was restored. There has been no recurrence of the infection during 18 months.

CASE 8 M F, female, aged 32 years. Postabortal sepsis. Series No 1030.

Five days before admission to the study, this patient had been relieved of a threatened abortion by a dilatation and curettage. Her temperature rapidly rose to 106 degrees, where it stayed for 3 days in spite of sulfadiazine, penicillin, and streptomycin. There was a prompt response to bacitracin in a dosage of 20,000 units every 6 hours. Within 4 hours the patient began to have a sense of well being. All attending doctors believed that bacitracin saved her life. Aerobic cultures which were made of the cervical discharge showed no growth, but the infecting organism was believed to be an anaerobic streptococcus.

CASE 9 L S, male, aged 58 years. Bronchiectasis. Series No 6010.

This patient had an 8 year history of bronchiectasis and emphysema which had failed to respond to penicillin and sulfadiazine. The penicillin caused a

severe reaction and it had to be discontinued. Cultures from the sputum yielded a group A hemolytic streptococcus and a nonhemolytic streptococcus which were susceptible to both penicillin and bacitracin. He was given 22,000 units of bacitracin every 6 hours for a period of 2 weeks. During this period of treatment the sputum decreased from 1 cubic centimeters to 20 cubic centimeters per day. A month later he had no purulent sputum and was able to return to work.

CASE 10 W D, male, aged 20 years. Cellulitis following human bite. Series No 5010.

A 2 day history of human bite, involving lacerated wounds in the soft tissues of the chest wall and the distal phalanx of the index finger, yielding on culture a mixture of organisms, with swelling, redness, pain, tenderness and fever, responding dramatically to systemic bacitracin therapy in a dosage of 6,000 units every 6 hours for 4 days. Within 24 hours practically all of the tenderness and pain disappeared and the cellulitis had subsided.

CASE 11 E R, male, aged 6 years. Cellulitis of leg. Series No 5029.

This patient had an extensive cellulitis of the leg with inguinal lymphadenitis and a high fever, as well as redness, pain, tenderness, and a blistering of the skin. The response to treatment with bacitracin with 10,000 units every 6 hours was dramatic with complete clearing of the lesion in 3 days. The cultures yielded a highly sensitive gram negative bacillus which was resistant to penicillin but susceptible to bacitracin. The patient left the hospital after a period of 6 days.

CASE 12 G S, male, aged 4 years. Cellulitis of leg. Series No 5032.

This patient came into the hospital with a history of very rapidly developing cellulitis of the leg all the way up from the ankle to the knee with a severe toxemia and inguinal adenitis. There was swelling, redness, pain, and a fever of 105.6 degrees, all of which subsided dramatically within 48 hours following the administration of 20,000 units of bacitracin every 6 hours.

CASE 13 A G, female, aged 67 years. Post radiation cellulitis of chest wall. Series No 5030.

This patient had had a radical mastectomy months previously and had received a full course of postoperative irradiation, following which she developed an extensive cellulitis of the entire left half of the chest wall, front and back. The swelling extended down on to the abdominal wall and down the arm to the elbow. She was very toxic, running a high fever. She was given 40,000 units of bacitracin every 6 hours. Toxic symptoms disappeared in 18 hours and the temperature reached normal on the third day. Before treatment began the blood urea was 30.8 milligrams per cent and during the treatment it went up to 38.4 milligrams per cent. The urine showed hyaline and granular casts before bacitracin and 1+ plus albumin with an occasional granular cast appearing during treatment, but the casts promptly disappeared.

CASES ILLUSTRATING THE RESULTS OBTAINED
WITH "EARLY DEEP TANK BACITRACIN"
DURING THE SECOND PHASE OF THE STUDY

CASE 14 H B, male, aged 35 years Cellulitis
of neck Series No 1043

Two days before admission this patient developed an infection on the front of the neck over the larynx. He was given 500,000 units of penicillin, but the infection continued to spread during the night until there was a zone of cellulitis all around the front of the neck extending down to the anterior chest with a small opening through the skin over the larynx where some necrotic tissue was seen. Penicillin treatment was continued and 40,000 units of penicillin were injected in the local area without improvement. Because of the rapid spread of the infection, it was thought advisable to start him off with a large dose of bacitracin and 38,000 units from lot No 480210 were given and repeated twice at 4 hour intervals. His temperature began to come down after the third dose, so the interval was increased to 5 hours for the fourth dose and to 6 hours for the fifth dose. Thereafter it was continued every 6 hours. On the third day the cellulitis in the neck had almost entirely subsided, indicating a favorable response to bacitracin. No cultures were taken, but the condition behaved like a hemolytic streptococcal cellulitis. However, on the third day he became nauseated and vomited several times, so bacitracin was stopped after 9 doses with a total of 342,000 units. On the third day his urine showed 2 plus albumin and a few red and white blood cells. On the fourth day this had increased to 3 plus albumin, but he felt well enough to go home. However, after his return home he complained of nausea, vomiting, and lethargy. He then reported that he had voided only a few ounces of urine. When these symptoms continued for 2 days, it was thought best that he should return to the hospital. However, with expectant treatment his urinary output gradually increased until on the eighth day he was voiding over 1 liter and on the tenth day it reached 2,340 cubic centimeters. The nonprotein nitrogen reached a peak of 117 milligrams per cent on the day after his readmission to the hospital, but on the ninth day it was down to 43 milligrams per cent and he left the hospital on the twentieth day with all of his renal function restored to normal. Later examinations have shown no residual evidences of kidney damage. (Table IX illustrates the study of his renal function.)

CASE 15 W D, male, aged 18 years Cellulitis
of neck Series No 1047

Four days before admission to the clinic the patient developed two furuncles on the chin. Penicillin was injected locally in a dosage of 2,000 units per cubic centimeter and on the following day some necrotic tissue was extruded from each lesion. This local treatment was continued and the redness and swelling subsided slightly but on the ninth day of the infection, swelling, redness and induration recurred and rapidly increased. Penicillin was then given

Fig 1, left Roentgenogram of Case 6 showing osteomyelitis around the lower screw holes in the bone graft

Fig 2 Roentgenogram of Case 7 showing osteomyelitis of the third metacarpal bone in actinomycosis of the hand

intramuscularly, but this was followed by an itching rash over the neck and the upper part of the trunk, and the local lesions showed no evidence of improvement. The patient then stated that 6 months before he had had two injections of penicillin without any reaction and this was thought to be a sensitivity response. Cultures of the wounds showed a coagulase positive hemolytic *Staphylococcus aureus*, which was susceptible to both penicillin and bacitracin. He was given bacitracin in a dosage of 20,000 units from lot No 480212 every 6 hours and the local wounds were irrigated with bacitracin solution containing 500 units per cubic centimeter. The next day he was definitely better. The swelling had decreased. The improvement during the next day was dramatic indeed and on the following day he was so much better that he was allowed to go home. During his hospitalization the urine did not show any albumin and the blood urea nitrogen remained at the low level of 12 milligrams per cent. The phenolsulfonphthalein was 65 per cent on the second day and 80 per cent on the fourth day. When he came to the clinic on the day after his discharge from the hospital the inflammation had further subsided, but he reported that he felt nauseated and had vomited. The urine then showed a 3 plus albumin, 4 plus glucose with clumped white cells and 5 to 6 red cells per high power field. He was admitted to the overnight ward and on the following day his blood urea nitrogen was 21 milligrams per cent, but the albumin, glucose, and cellular elements began to decline. During the following day he continued to improve, his appetite returned and his urine was in good

The table shows the changes in the albumin and microscopic picture, the high blood urea nitrogen and low specific gravity following the administration of one of the most toxic lots. Restoration, however, was complete in a month.

volume. The albumin fell to 1 plus, glucose was negative, and the red blood cells were rare. Four days after discharge the blood urea nitrogen had returned to normal.

CASE 16 J R, male, aged 21 years. Paronychia of toe, cellulitis of foot and inguinal lymphadenitis. Series No 7004.

Four days before admission this patient developed a paronychia of the large toe with a rapid spread of redness, swelling, pain and tenderness on the dorsum of the foot and with tender inguinal lymph glands. Cultures showed a hemolytic streptococcus sensitive to both penicillin and bacitracin and a coagulase positive *Staphylococcus aureus* sensitive to bacitracin but resistant to penicillin. He was put on 20,000 units of bacitracin from lot No 471212, and the nail was removed. There was a prompt clinical response within 72 hours. On the fifth day the nonprotein nitrogen rose from an initial level of 32 milligrams per cent to 42 milligrams per cent and the phenolsulfonphthalein fell from 70 per cent to 54 per cent. Renal cells were still present on the thirteenth day, but thereafter signs of nephrotoxicity cleared.

CASE 17 M C, male, aged 17 years. Cellulitis of the hand and arm with axillary lymphadenitis. Series No 7011.

Six days before admission this patient had an accidental avulsion of the skin over the dorsum of the right hand and the wound promptly became red, swollen, tender, and obviously infected. Two days before admission a painful lump developed in the axilla with red streaks coursing up from the area of infection on the hand. He was given bacitracin in a dosage of 11,800 units from lot No 471231 every 6 hours. The cultures showed hemolytic streptococcus, susceptible to both penicillin and bacitracin, and coagulase negative *Staphylococcus aureus* susceptible to bacitracin and resistant to penicillin. The infection promptly subsided and resolved completely after 96 hours. On the fourth day of treatment, casts and renal cells appeared in the urine, but there were no red cells. The nonprotein nitrogen, starting with 39.9 milligrams per cent before bacitracin, rose quickly to 61.5 milligrams per cent on the fourth day. The phenolsulfonphthalein fell slightly during this time. The patient left the hospital on the fourth

day with no complaints except slight anorexia and malaise. After leaving the hospital he steadily improved and soon went back to active duty in the Army without any evidence of any kidney damage.

CASES ILLUSTRATING THE RESULTS OBTAINED DURING THE THIRD PHASE OF THE STUDY WITH "LATER DEEP TANK" BACITRACIN MEETING THE FOOD AND DRUG ADMINISTRATION TOXICITY TEST OF LD 50/500

CASE 18 S L, female, aged 79 years. Suppurative arthritis of hip after arthroplasty. Series No 1070

Three years before admission this patient had fallen and broken her hip. She was taken to a local hospital and the fracture was pinned, but this treatment was not successful and an arthrotomy was performed. The wound became infected and continued to drain for a long time through the operative site and a spontaneous sinus developed on the inner surface of the thigh. This sinus drained profusely over a period of 3 years. Culture then yielded a *Staphylococcus aureus* susceptible to bacitracin but resistant to penicillin. An x-ray plate taken after lipiodol injection revealed that there was an abscess cavity extending upward from the sinus opening into the hip joint where there was a large fragment of the femoral head (see Fig 3). Bacitracin was instilled through the sinus for several days and then through an anterior approach the head of the femur was removed from the hip joint. She was treated intramuscularly with 10,000 units of bacitracin every 6 hours and the sinus was irrigated daily with a solution of bacitracin containing 500 units per cubic centimeter, without any evidence of toxicity except light nausea. The anterior wound healed rapidly and after 5 weeks the sinus in the groin closed and has remained healed. There has been a steady increase in the function of walking, with the infection apparently completely arrested.

CASE 19 P W, male, aged 13 years. Staphylococcus septicemia with acute osteomyelitis of the femur. Series No 1066

This boy had been playing soccer on the day before admission and had fallen down a number of times. He awoke early the next morning complaining of pain in the region of the left hip. He felt nauseated and vomited and 3 hours later had a short chill. His temperature during the day gradually rose to 103.6 degrees and he appeared very toxic and in great pain. There was tenderness well localized to the posterior region of the hip joint, but the joint itself was free, although extremes of flexion and extension caused pain. He was brought into the hospital and a blood culture was taken. He was given 100,000 units of penicillin and 50,000 units every 3 hours during the night. The next morning his temperature was 104 degrees. Tenderness was still present, so the dosage of penicillin was increased to 100,000 units every 3 hours. On the third day he seemed a little better. There was less tenderness

Fig 3. Lipiodol injection of a suppurative arthritis of the hip in Case 18 following arthroplasty for a comminuted fracture. Part of the head of the femur is seen acting as a sequestrum.

and muscle spasm, but with the diagnosis and the organism still in doubt, he was given sulfadiazine along with the penicillin, but together they failed to control the infection. On the fourth day his pain, tenderness, and Kernig's sign reappeared, indicating a reactivity of the process. The blood cultures taken on admission and on the first day after admission both grew out on the fourth day revealing a coagulase positive hemolytic *Staphylococcus aureus*. It was then obvious that he had a staphylococcus septicemia with an osteomyelitis probably of the neck of the femur. On the fourth day when the nature of the organism was known, sulfadiazine was stopped and he was given bacitracin in a dosage of 200 units per kilogram of body weight (5,250 units) every 6 hours. Blood culture taken on that day showed no growth. On the fifth day the bacitracin dosage was doubled. That day the sensitivity test revealed that the organism was resistant to penicillin but susceptible to bacitracin, explaining the failure of penicillin to bring about the expected prompt response. However, it was demonstrated that there was a synergism between bacitracin and penicillin, which permitted 1/10 of the growth inhibiting dose of one, plus 1/32 of the growth inhibiting dose of the other to prevent

Fig 4 Temperature curve of Case 19 showing failure of penicillin to control the infection and resolution when bacitracin was added to the therapy

Fig 5 Temperature curve of Case 21 showing rising temperature and increasing mass in popliteal space not controlled by penicillin but responding to bacitracin

the growth of the organism in vitro. Thereafter all symptoms and signs rapidly subsided (Fig 4). During this treatment the nonprotein nitrogen rose from 30 to 49 milligrams per cent, but with continued treatment it came down again to 32 milligrams per cent at the end of treatment and thereafter dropped back to normal (see Table X for a résumé of his toxicity studies). There were no clinical symptoms of toxicity and this rise in nonprotein nitrogen was not sufficiently alarming to warrant cessation of treatment. It is likely that in this case the favorable response was due to a synergistic action between the two antibiotics. On the tenth day the x-ray film revealed a suggestive area of beginning rarefaction in

the neck of the femur, but on subsequent x ray films this disappeared. However, the clinical diagnosis was unmistakable.

CASE 20 S T, female, aged 62 years. Post craniotomy wound infection with subdural abscess. Series No 1100.

Three weeks before treatment began, a cortical ablation had been done of the right frontal lobe through an osteoplastic craniotomy for a depressive type of schizophrenic psychosis. Postoperatively she received 50,000 units of penicillin every 3 hours for 8 days and 300,000 units of duracillin a day for 7 days. Two days after stopping this treatment the patient became drowsy and fluctuation of the scalp

This table shows the moderate but transient evidence of kidney irritation with rise and fall of nonprotein nitrogen during treatment

Fig 6

Fig 6 Roentgenogram of Case 21 showing progressive breakdown of the bone

Fig 7

Fig 7 Later films of Case 21 showing progressive regeneration of the bone with no clinical signs or symptoms

revealed an underlying abscess. Penicillin was increased to 150,000 units every 3 hours, but this failed to control the infection. The wound was opened and a large quantity of pus was released yielding a staphylococcus susceptible to bacitracin but resistant to penicillin. The wound was opened further and the bone flap removed. A subdural abscess was found. She was given 10,000 units of bacitracin in 10 cubic centimeters of saline instilled into the wound through a sterile catheter every 3 hours. Bacitracin was also given intramuscularly in a dosage of 10,000 units every 6 hours for a period of 10 days. The local instillation was continued for a month, the sinus at the catheter site remaining open. During this treatment the blood urea nitrogen tests remained essentially unchanged. The sinus persisted until it was re-explored and a small piece of necrotic tissue which was acting as a foreign body was removed. With a continuation of local bacitracin the sinus promptly closed.

CASE 21 W R, male, aged 10 years. Staphylococcus aureus septicemia with acute osteomyelitis of the femur. Series No 1039.

This boy had a sudden onset of pain in the popliteal space of the left leg followed by inability to walk and high fever. On admission to the hospital the next day his temperature was 106 degrees. He had diffuse pain and tenderness in the region of the lower end of the left femur. He was immediately put on penicillin in a dosage of 100,000 units every 3 hours and sulfadiazine 0.5 grams every 4 hours. His temperature stayed up for 24 hours and then came down toward normal, but then rose again and reached 104.4 degrees on the fourth day. During this time there was a slow but steady development of a mass in the popliteal space. Blood culture on admission showed a hemolytic Staphylococcus aureus resistant to penicillin but susceptible to bacitracin. Therefore all other treatment was stopped and he was given bacitracin in a dosage of 400 units per kilogram of body weight. It was thought that the

popliteal mass was an abscess which would require drainage, but following bacitracin treatment the mass steadily decreased in size, the function of the leg rapidly improved and he was soon able to return home, having shown no evidence of renal toxicity. A series of x-ray films showed an area of osteomyelitis in the lower end of the femur with a progressive breakdown of bony tissue, then a standstill and a gradual restoration (see Fig 5). In this case the penicillin plus the sulfadiazine controlled the septicemia, but they could not control the local process. Nevertheless bacitracin stopped its progress and caused its steady resolution. He has been perfectly well for 6 months so far. Figure 6 shows progressive breakdown and Figure 7 regeneration of bone.

CASE 22 M B, female, aged 6 weeks. Staphylococcus septicemia and meningitis with metastases in lungs and subcutaneous tissues. Series No 1080.

This baby was born prematurely but left the hospital after 3 weeks weighing 5 pounds. Four days after discharge the right side of the face began to swell and there was a bloody nasal discharge. She was taken to a suburban hospital where she was given penicillin and streptomycin without any appreciable effect. She was therefore brought to the Babies Hospital in New York, where the penicillin dosage was increased and where blood culture revealed the hemolytic Staphylococcus aureus septicemia and a lumbar tap revealed meningitis. The dosage of penicillin was increased and this was also given intrathecally but without effect. Streptomycin was also given intrathecally and then aureomycin was started, but all of these treatments failed to control the infection. Metastatic abscesses appeared in the back and on one hand and one foot. Several areas in the right lung field suggested a pneumonitis with early abscess formation. The baby's neck was stiff and she was semicomatose when bacitracin was called for. She was started on 400 units per kilogram of body weight every 6 hours intramuscularly. It

Fig 8 Temperature curve of Case 22 showing failure of septicemia and meningitis to respond to penicillin, sulfadiazine, streptomycin, and aureomycin with prompt response when intramuscular and intrathecal bacitracin was added

was also given intrathecally twice a day in a dosage of 500 units and it was instilled into the abscess of the face through a plastic catheter in a dosage of 500 units per cubic centimeter. Two days after beginning treatment the patient came out of her coma. The blood and spinal fluid cultures became normal on the fourth day of bacitracin treatment and thereafter she went on to a complete recovery (see Fig 8). The incipient abscesses of the lungs resolved completely (see Figs 9, 10). There was a moderate rise of the nonprotein nitrogen from 30 to 38 milligrams per cent, but it returned promptly to 31 milligrams per cent.

It was generally agreed that bacitracin had saved this patient's life.

CASE 23. I. R., female, aged 30 years. Pansinusitis with undermining burrowing ulcer of face and orbits. Series No. 1072.

This patient had had an infection of the bones of the face starting 5 years before as a pansinusitis which spread from the antrum up into the right orbit, requiring the removal of the eye. Gradually the process then spread to the left orbit. All of the small bones of the face were involved in the destruction. She was given several series of penicillin treatments without any effect and also a long period of aureomycin. This case had many of the features of undermining burrowing ulcer. However the characteristic microaerophilic hemolytic streptococcus was not found. The only organism constantly present was a *Staphylococcus aureus*, susceptible to bacitracin but resistant to penicillin (Fig 11 shows the lesion at this time). Bacitracin was then started in a dosage of 10,000 units every 6 hours. It was also used locally in the form of an ointment and a solution which was applied on gauze packing. It was obvious within a few days that the spread of the

infection had stopped. After a month of treatment with only partial improvement because the infection was still active in the left orbit and beneath the eyelids, it was decided after 50 days of bacitracin treatment to remove all of the diseased tissue and to cut back the undermined margins so as to permit a more complete contact of the medication with the infected tissue. At the same time the systemic dosage of bacitracin was increased to 20,000 units every 6 hours. Hereafter the whole wound cleaned up with remarkable rapidity, new skin grew in from the margins and on the twenty-first day the entire area was covered with pinch grafts. These took everywhere except in several small areas where there was residual nasal mucosa (see Fig 12). The areas were then curetted and the defects covered with similar grafts. These also took satisfactorily and the area was soon completely covered.

This patient has the record for prolonged treatment with bacitracin. For 50 days she received 40,000 units a day and for 85 days 80,000 units a day. The total systemic bacitracin was 9,360,000 units. About 800,000 units were used locally during the course of treatment. The nonprotein nitrogen stayed at a remarkably constant level, being 23 milligrams per cent before beginning bacitracin and 28 milligrams per cent at the end of treatment. This is unquestionably a case in which the life of the patient was saved and the infection brought under control by bacitracin. Standard doses of bacitracin were continued for almost 5 months with little or no evidence of kidney damage.

Fig 9 Roentgenogram of Case 22 showing metastatic abscesses of the lungs before bacitracin therapy

Fig 10 Roentgenogram of Case 22 showing clearing of lung lesions after bacitracin

CASE 24 D M, male, aged 60 Gangrenous ulcer of back, flank, and buttock. Series No 1092

Five weeks before admission this patient developed a pleuritic pain in his left chest, which was strapped with broad adhesive to which his skin was sensitive. The skin became blistered like a second degree burn and the whole area then became infected with a very peculiar type of gangrene. This spread rapidly all over the back, into the left flank and down on the buttock. The infection failed to respond to penicillin, sulfadiazine, and streptomycin (Fig 13 shows the lesion when it was first seen by FLM). He was given bacitracin in a dosage of 10,000 units every 6 hours and in 48 hours it was obvious that the spread of the infection had come to a standstill. He was brought to Presbyterian Hospital in New York from a suburban hospital and the dosage of bacitracin was doubled. There was moderate but transient evidence of kidney irritation, but no significant rise in nonprotein nitrogen. The gangrenous tissue was excised and on the tenth day two-thirds of the area was covered with skin grafts, and 10 days later the remainder. There was an almost complete take of these grafts and soon they grew out epithelium from the margins and rapidly fused together (see Figs 14 and 15). His recovery, however, was complicated by the development of two pressure sores, which occurred during the immobilization period after the grafting. The cultures yielded not only a hemolytic *Staphylococcus aureus* and non-hemolytic streptococcus, which were resistant to penicillin but susceptible to bacitracin, but also an *Aerobacter aerogenes* and later both proteus and pyocyanus were recovered from the large area. The staphylococcus and streptococcus were brought under control by bacitracin, the proteus by parachlorophenol and the pyocyanus by sulfamylon.

Everyone was impressed by the rapid control of the infection with bacitracin and believes that this saved the patient's life.

CASE 25 M B, female, aged 34 years Progressive postoperative bacterial synergistic gangrene. Series No 1101

This patient was admitted to a suburban hospital in the early stages of labor, but after 16 hours there was no progress and a cesarean section was performed. The patient was given 60,000 units of penicillin prophylactically and 2 grams of sulfanilamide crystals were sprinkled throughout the wound, which was then closed with silk stay sutures protected by rubber tubing. Forty thousand units of penicillin were given every 3 hours for 6 days and 1 gram of sulfadiazine was given every 4 hours for 3 days. On the eighth day, in spite of these antibacterial agents, the wound revealed an infection with redness, swelling, and small vesicles which gradually developed into bullae, evidently starting around the retention sutures.

At this time the whole wound became inflamed with areas of dusky skin somewhat raised from the surface, indicative of the early stages of bacterial synergistic gangrene. Cultures were taken which revealed the microaerophilic nonhemolytic streptococcus, *Staphylococcus aureus*, and *Escherichia coli*. The stay sutures were removed. The patient was put on bacitracin in a dosage of 10,000 units every 6 hours and it was also applied locally on wet com-

Fig 12 Relatively prompt control of the infection in Case 23 by excision of undermined margins followed by systemic and local bacitracin permitting successful skin grafting on the 21st day.

Fig. 13 The extent and nature of the infection in Case 24 before treatment with bacitracin

presses in a concentration of 500 units per cubic centimeter. Within 48 hours the spread of the infection ceased and the whole process came under control. Thereafter resolution was rapid without any necrosis of tissue.

It was generally recognized that the early diagnosis and the early administration of bacitracin completely controlled the infection and saved the patient from the development of extensive gangrene, after prophylactic penicillin, sulfadiazine, and streptomycin failed to do so.

CASE 26 G. B., male, aged 39 years. Cellulitis of the scalp. Series No. 2022.

Four days before admission this patient was hit on the head with a brick. Three days later he noted swelling of the scalp and of the tissues around his

Fig. 14 Control of infection in Case 24 and successful postage stamp grafts on two thirds of denuded surface

left eye. On admission to the hospital his temperature was 102 degrees and there were numerous lacerations in the left frontal region of the head which were surrounded by a zone of cellulitis and edema extending down to the ear posteriorly and the zygoma in front. The eye was almost closed and the lids were light purplish in color. The patient was given 10,000 units of bacitracin every 3 hours for 3 days. During this time the cellulitis and edema rapidly subsided and the patient was discharged 4 days later. Although albumin appeared in the urine the phenolsulfonephthalein filtration was normal throughout. There was a mixture of organisms including hemolytic streptococcus, *Staphylococcus aureus*, *Bacillus melaninogenicum*, and several other organisms not fully identified.

This was considered a brilliant response of the infection to bacitracin.

CASE 27 S. D., male, aged 51 years. Cellulitis of face, diabetes. Series No. 2019.

Seven days previously this patient had squeezed a furuncle on his left cheek. Following this the area became greatly swollen and indurated. Mild diabetes had been present for about 15 years. On admission the left side of the face was involved in a severe cellulitis of the entire parotid region, the left maxillary and submental area, and an extension ran down along the sternocleidomastoid muscle, with an area of fluctuation at the site of the furuncle. The area was incised and drained. Bacitracin was given in a dosage of 10,000 units every 6 hours. The patient had a 3 plus albumin before treatment, but this decreased during therapy and the red cell white cells, and sugar disappeared. Bacitracin was stopped after 5 days, when the temperature was normal.

This was considered an excellent response to bacitracin.

CASE 28 C. H., female, aged 13 months. Cellulitis of thigh. Series No. 5040.

Three days before admission this patient was bitten by a mosquito and the area very rapidly developed

stage in the healing process following the administration of bacitracin therapy

Fig 18 The final healing in Case 29 following partially successful secondary closure

Fig 17 The control of the infection in Case 29 and a an extensive cellulitis involving all of the anterior portion of the thigh. The patient's temperature was 104 degrees on admission to the hospital and there was swelling, redness, pain, and tenderness throughout the thigh

She was put on 5,000 units of bacitracin every 6 hours and the temperature fell abruptly. It was almost normal on the afternoon of the first day of treatment and on the following day reached normal and remained there with complete resolution of the

Fig 19

Fig 20

Fig 19 The extent and nature of the undermining burrowing ulcer of the thigh in Case 30

Fig 20 The final healing in Case 30 following bacitracin therapy

inflammatory process. No opportunity was given for cultures. A few red and white cells appeared in the urine but there was no albumin and no rise in the nonprotein nitrogen.

CASE 29. I. W. male, aged 70 years. Chronic undermining burrowing ulcer of abdominal wall. Series No. 5253.

Three weeks before this patient had had an appendiceal abscess drained through a stab wound in the right flank. Immediately thereafter he developed a severe infection of the abdominal wall which spread through the subcutaneous fat down into both groins and over into the left flank with undermined skin flaps measuring 2 or 3 inches in various places. The muscle was not involved and the infection had all of the characteristics of the undermining burrowing ulcers (see Fig. 16). The microaerophilic hemolytic streptococcus was found along with several secondary contaminating organisms. The streptococcus was susceptible to bacitracin but resistant to penicillin. He was put on bacitracin in a dosage of 20,000 units every 6 hours systemically and it was used in the form of an ointment locally containing 1,000 units per gram. Improvement was rapid and remarkable. Further extension of the infection was immediately halted and healing began almost immediately. After 10 days the wound was clean and a secondary closure was attempted but this was only partially successful because of the secondary contaminants (see Fig. 17). However thereafter the wound healed by secondary intention (Fig. 18) and it was the general opinion that bacitracin had saved this patient's life.

CASE 30. M. P. female, aged 41 years. Undermining burrowing ulcer of thigh. Series No. 5051.

Two weeks before admission to the hospital this patient developed a pimple on the anterior surface of the left thigh. She picked it and it began to enlarge. On admission there was a large ulcer about 4 inches in diameter on the anteromedial aspect of the left thigh in the upper third (see Fig. 19). The ulcer was excised and warm compresses were applied. Penicillin and sulfadiazine were given systemically, but there was complete failure of the ulcer to heal. Thereafter the margins of the ulcer became undermined almost up to the inguinal ligament above and to a lesser degree all around the other margins, giving the characteristic features of the chronic undermining burrowing ulcer. Intramuscular bacitracin was started in a dosage of 20,000 units every 6 hours and continued for 10 days. Bacitracin ointment was applied on fine meshed gauze. Within 24 hours improvement was obvious and in 72 hours the whole ulcer was covered with clean granulation tissue. The flaps thereafter rapidly became adherent and partial secondary closure and a skin graft was then done. The portion which could be sutured healed primarily and there was about an 85 per cent take of the skin graft (see Fig. 20). The urine remained normal throughout treatment and the nonprotein nitrogen fell from 17 to 12 milligrams per cent.

This was considered a most dramatic cure.

SUMMARY

1. Two hundred and seventy cases representing a wide variety of surgical infections and certain medical infections have been treated with intramuscular bacitracin over a period of 22 months by 6 different observers in different geographical areas of the country.

2. These cases have been studied in a systematic form manner with careful consideration of each of the factors involved, and the results of treatment have been divided into 4 categories: "excellent," "good," "questionable," and "no effect." The first 2 are considered "favorable" and the last 2 "unfavorable."

3. Records of these cases have been transferred to summary sheets which have been carefully reviewed in a central office and the data have been subjected to critical analysis.

4. About three-fifths of these cases had failed to respond to other antibacterial agents, yet 55.6 per cent then responded favorably to bacitracin. These are called "salvaged cases."

5. About two fifths of these cases had had no previous treatment and 78.1 per cent have responded favorably to bacitracin.

6. These two groups are not comparable because the patients without previous treatment in general had been ill for a shorter period of time when bacitracin treatment was started than the patients previously treated by other methods.

7. The bacteriological studies indicate that the majority of these infections were due to a mixture of organisms.

8. The favorable results with bacitracin were obtained in these mixed infections almost as readily as in the pure infections, owing to its wide antibacterial spectrum and the absence of any inactivating substance such as penicillin has to face in penicillinase.

9. Tests for susceptibility of the organisms associated with these infections to bacitracin and penicillin, showed that the majority were susceptible to both drugs but where there was a difference, the ratio was 10 to 1 in favor of bacitracin. The evidence seems to indicate that this is due to the fact that many of the patients had built up a resistance to penicillin during previous treatment with that drug.

10. The bacitracin used in this study was manufactured by Company A by the surface

growth method and by Company B by the deep tank method

11 Circumstances have divided this study into 3 phases. First, the period when the patients were treated by the "surface growth bacitracin" and evidences of nephrotoxicity were minimal and inconsequential. Second, the period when patients were treated by the "early deep tank bacitracin" and evidences of nephrotoxicity were disturbing. Third, the period when patients were treated by bacitracin meeting the Food and Drug Administration toxicity test of an LD₅₀ of 500 units for a 20 gram mouse, during which phase confidence in the efficacy and, in large measure, the safety of bacitracin has been restored.

12 Brief outlines and photographs have been presented which illustrate some of the cases of patients who have been successfully treated during these 3 phases of the study.

THE MECHANICAL HEART-LUNG SYSTEM

J JONGBLOED, M D , Utrecht, The Netherlands

EARLY in 1948 I published the reports of the results obtained from experiments in dogs, performed by myself and staff and dealing with the use of an artificial heart with artificial lungs

In our opinion an artificial heart must replace the organic heart temporarily, in other words it must maintain circulation throughout the body. From the interesting work of Bjork it appears that with the Crafoord method only the brains of dogs are perfused. As other parts of the organism can be left without circulation for some 15 minutes, the venae cavae may then be clamped during such an interval of time so that the heart cavities become free of blood, intracardial operations are then possible.

The question arises, however, whether or not parts such as the spine, the heart muscle, or other organs can really withstand a lapse in circulation without harm. Even if that were possible, with the Crafoord method, which may be very useful for some special purposes, one is always handicapped by the time element. Our method, on the other hand, permits the maintenance of complete circulation (to the brain, to the spine, to the heart muscle, the bronchial circulation to the lungs, to the endocrine organs, to the liver, to the kidneys, etc.). Only venous blood does not enter the heart and the pulmonary circulation. The cavities of the heart are empty of blood, or nearly so.

We realize that with our broader conception of the artificial heart additional difficulties must be met. First about five times as much blood per unit of time must be oxygenated as in brain perfusion. Second, the persistence of the coronary circulation might make intracardiac operations more difficult, we have no choice, however. A prolonged lapse in coronary circulation undoubtedly will cause damage to the heart muscle (fibrillation), especially in the presence of heart weak-

ness. If absolutely necessary the heart surgeon may interrupt the coronary circulation for a short time or he may aspirate the venous coronary blood when the right heart cavities are opened. We have accepted these difficulties readily since the great advantage of our method is that in principle we are not limited for time, we are not restricted to minutes, we may go on for hours and we hope eventually for days. The use of our heart-lung system therefore will not be restricted to operations upon the heart and perhaps some other operations, but the apparatus may possibly be used also as an artificial heart to relieve the organic heart in its task of overcoming an acute process (diphtheria) and as well to replace the lungs temporarily in cases in which a few days will suffice for our modern drugs to overcome infection (for example, in cases of severe pneumonia in the remaining lung after pneumonectomy).

Early experiments in dogs In preliminary experiments we studied the behavior of the heart and the lung during and after the use of the mechanical device. In these experiments the thorax was widely opened. Cannulas were inserted in both venae cavae and in the aorta. After the venae cavae were clamped near the heart the venous blood was pumped to an oxygenator and from here into the aorta via the side branches of the cannulas.

From these experiments we learned that the electrocardiogram of the heart empty of blood was almost unchanged, and that the heart and the lungs resumed their normal functions immediately when the mechanical device was stopped and the clamps were removed, even when they had been empty of blood (except for the coronary and the bronchial circulation) for more than an hour.

In the second series of experiments we studied methods of applying the artificial heart lung with as little damage to the animal as possible. The following method was adopted

From the Physiological Institute of the University of Utrecht

Fig 1 Schematic diagram of the apparatus Shunt in use, venous tube coming from the subject (under, left) and arterial tube leading to the subject (under, right) both clamped In the shunt are 2 filters, a filling and an outlet tube Further from left to right rotameter (volume per minute indicator), one venous pump with membrane pump, one spiral oxygenator, assembling tube with bubble aspirator, regulating reservoir, waterbath with one arterial pump, arterial leading with buffer vessel, filter, and pressure meter

A catheter was introduced through the external jugular vein into the vena cava superior close to the heart A second catheter was brought up high in the vena cava inferior through the femoral vein Both catheters were connected with a pump (type Dale-Schuster), which sucks the blood from the venae cavae Careful adjustment of this pump made it possible to aspirate all the blood from the venae cavae just before it enters the heart The same pump drove the blood to an oxygenator By a second pump the collected oxygenated blood was forced into the femoral arteries in which T cannulas were inserted This blood proceeded in the normal direction to the distal parts of the hindlegs and in the abnormal direction in the aorta toward the heart However, as there was no blood in the left ventricle, the artificial aortic pressure was higher than the pressure in the right ventricle and the aortic valves remained closed From the aorta the blood flowed normally into the different arterial branches, including the coronary arteries Thus in performing only the simple operations on the vessels necessary in order to insert the catheters and the cannulas, it proved to be possible to maintain artificial circulation and respiration If treated aseptically the animal survived without any sign of distress We have a dog on which the artificial heart-lung system

Fig 2 The 6 venous pumps with their inlet tubes, membrane pumps and motor, which also drives the spiral oxygenators

was applied 1 year ago, and the animal behaves still as normal as any dog This probably is the first dog in the world who has lived an interval of 2 hours without using his own heart and lungs

Our results were so convincing and the method and apparatus so simple, that I decided to construct a bigger apparatus for future use in man

General construction of the apparatus A system of pumps (right heart) sucks the venous blood from the subject and drives it to the oxygenators The oxygenated blood is collected in a reservoir A second system of pumps (left heart) forces the oxygenated blood through a heating device back into the subject (see schematic diagram, Fig 1, from left to right)

The right heart pump system A modification of the Dale-Schuster pump is used (Fig 2) The unit consists of 6 single pumps driven by a central 6-fold crankshaft The movements of the membranes are transported by air to the finger stalls The glass housings of these finger stalls have inlet and outlet valves, consisting of amber or glass balls in a ground glass fitting Thus the blood comes in contact only with rubber and glass, there are no metal and no frictionizing parts The frequency of the pumps can be regulated by changing the speed of the electric motor driving the shaft, the volume per stroke of each pump by a divided tap, which provides a smaller or greater leak in the air-transport system, a method also used by Gibbon The

Fig 3 The 6 oxygenators with the 2 assembling tubes leading to the reservoir Under left, the main venous tube, on the table, the handles to clamp the 6 venous tubes

six pumps work alternately, so that constant suction from the caval vein ensues. The volume per minute can be constantly read on a rotameter. At a frequency of 70 per minute, and a volume per stroke of 10 cubic centimeters per pump, the volume per minute is $7 \times 6 \times 10$ cubic centimeters = 42 liters. The pumps are mounted on a detachable metal strip and can easily be sterilized together with their tubing.

The spiral oxygenator As it is practically impossible to insert the organic lungs in an artificial heart circuit, the use of a mechanical heart calls for the use of artificial lungs. Our artificial lung consists of 6 equal parts, one for each right-heart pump (Fig 3). To avoid the disadvantages of the usual oxygenators we developed a new type of relatively small size and without rapid moving parts, which may cause hemolysis and foaming. Each oxygenator consists of a rigid tube of some suitable plastic material with an internal diameter of 18 millimeters and about 10 meters long. This tube is bent into the shape of a spiral, or to be exact, it forms 3 layers of spirals one in the other, to save space. Both the beginning and end of the tube lie in the central axis of the spiral. The six spirals are mounted in a frame, with their axis pointing slightly downward. They turn about this axis, synchronously with the pumps. Now if a quantity of blood is in the

first winding of a spiral it will move all through the spiral and at last come out at the other end. (A similar principle is used by Kolff for diffusion purposes in his artificial kidney (6).) As the blood passes through the spiral tube it will adhere to the wall and form a thin layer. Oxygen (with carbon dioxide) streams constantly through the tube and the blood is readily oxygenated. The volume per stroke of each pump proceeds during one revolution from the first coil of its spiral to the second coil, while simultaneously a new volume of blood is pumped into the first coil and so on. So the stroke volumes of blood pass through the spiral, one after the other, becoming gradually oxygenated.

The oxygen intake in one passage through the spiral on the average is very good, the saturation with oxygen rises for example from 60 to 90 per cent at a volume per minute of 700 cubic centimeters per spiral. This means that with a total minute volume of $6 \times 700 \text{ cc} = 42$ liters, the oxygen intake is $42 \times 60 \text{ cc} = 252 \text{ cc}$ per minute, which may be considered sufficient for a man in basal condition.

It is clear that the oxygen-intake will be greater the lower the saturation of the venous

Fig 4 The regulating reservoir, which prevents air from coming in the arterial system. Two (curved) inlet tubes and one outlet tube.

Fig 5 Overall view of the mechanical heart-lung device The tables are 80 cm wide.

blood With a venous saturation of about 20 per cent we found an oxygen intake of between 90 and 100 cubic centimeters per liter of blood The accompanying table presents some of our experimental figures in the range from 80 per cent to 50 per cent saturation of the venous blood

VENOUS SATURATION IN 80 TO 50 PER CENT RANGE

Venous saturation per cent	Arterial saturation per cent	Oxygen intake per liter c. c.
80	96	32
74	94	40
66	90	48
61	88	54
51	85	68

Even after the same quantity of blood had constantly passed the oxygenators for 2 hours and more, we could detect no appreciable hemolysis There was no foaming in the spirals

It is our opinion based on our observations that this new type of artificial lung offers much that is promising

The regulating reservoir The arterial blood from the oxygenators is collected in a glass reservoir (Fig 4), from which it is sucked away by the left-heart pumps To prevent the pumps from sucking air, which would cause air embolism in the subject, they stop auto-

matically when the blood in the reservoir has reached the lowest tolerable level After about 2 seconds the steady flow from the oxygenators has raised the level and the arterial pumps start their work again This automatic system to prevent air from coming into the arterial system is very simple the reservoir hangs in spiral springs and moves by its weight (which depends on the quantity of blood inside), a mercury contact It is practically not possible to make two sets of pumps which return absolutely the same volume per minute, and even if it were, both the venous return in the subject, as well as the arterial pressure may change a bit from time to time, which would make continuous regulation of the pumps still necessary It would of course be wrong if the volume per minute of the venous pumps were greater than that of the arterial pumps, because then the blood of the subject would gradually be accumulated in the reservoir For these reasons the arterial pumps are regulated in such a way that their minute-capacity is just a little greater than that of the venous pumps, then the apparatus functions automatically the arterial pumps will stop for a few seconds now and then, say once in some minutes, this time interval depending on the degree of exactitude with which the arterial pumps are adjusted

The left-heart pump system. The left-heart pump (shown at the right in Fig. 5) system consists of 6 pumps similar to those of the right-heart system. They work in two groups of 3 alternately, so that a real pulse results. A pulse seems to be necessary for good perfusion of the organism. The pumps with their inlet and outlet tubes are immersed in a waterbath kept at such a temperature (about 30°C) that the outcoming blood registers 37° degrees. The cooling of the blood in the oxygenators is, however, not more than $\frac{1}{2}$ to 1 degree at normal room temperature. The outlet tubes of the pumps join 3 by 3 to a larger tube. Parallel to each of these two tubes runs a tube with a fine filter so that the blood can be driven at will through or beyond the filters. The two tubes are connected with the two horizontal arms of a cross shaped glass tubing. The upper arm of the cross leads to a buffer-vessel, the upper opening of which is connected with a blood-pressure meter. The tube which leads to the two cannulas in the femoral arteries is connected to the lower arm of the cross. Of course the pressure to be exerted by the arterial pumps depends foremost on the circulatory resistance of the subject. By altering the leak of the membrane pumps it is easy to adjust the blood pumps so that the wanted volume of blood per minute is driven out against the prevalent pressure.

The arteriovenous shunt. From the main arterial tube a shunt tube leads to the suction-side of the venous pumps (Fig. 5). Parallel to this tube we mounted two filter-houses with fine filters. If the tubes leading from and to the subject are closed and the shunt tube is opened the blood circulates in the apparatus from the venous pumps through the oxygenators and the reservoir to the arterial pumps in the waterbaths and then through the shunt back to the venous pumps. Thus the apparatus is filled with oxygenated warm blood before it is applied to the subject. During this shunt circulation the blood is passed through the filters so that clots if there might be any in the blood are filtered out beforehand. So when the patient is prepared for operation that is when the catheters are inserted into the venae cavae superior and inferior (through a jugular and a femoral vein, respectively) and

the T cannulas are placed in the femoral arteries and when the connecting tubes having been filled with blood or saline are attached to the catheters and the cannulas has simply to open the connecting tubes to close the shunt and artificial circulation started.

As circulation is maintained with the filters in the main circuit may also be used during circulation through the shunt. These filters are of use only in so far as they may withhold clots which originate in the apparatus.

Adjacent apparatus. Each of the tubes leading to the venous pumps and also the inlet and outlet tubes of the arterial pumps are provided with handles so arranged that the tubes can be closed rapidly with one simple movement in case something might go wrong with the relative pump. We have had however, no trouble whatsoever during the hundreds of hours in which the system has been in use.

As already stated the blood does not foam in the apparatus but at the blood level in the assembling tubes, leading from the oxygenators to the reservoir some bubbles may appear. If they do the bubbles are easily sucked away to a vacuum vessel (Figs. 4 and 5).

The handling of the apparatus. As the apparatus is semiautomatic the handling is very simple and can easily be done by a man. Before use the dead space of the apparatus must be filled with blood (of course in future use in man it must be filled with blood of the same group as that of the patient) otherwise the blood taken to fill the dead space would lessen the volume of blood of the subject. It takes about 2½ liters of blood to fill the dead space. This may seem like a rather large quantity. Strictly speaking it could be less as the blood normally present in the lungs (in man about 1 liter) could be taken from the patient. However as blood especially human blood is easily obtained I think that the use of 2½ liters will not present a great difficulty. Except for the artificial lungs which hold about 1 liter, the dead space consists of the various tubes, the reservoir, the pumps and the heating system.

JONGBLOED MECHANICAL HEART-LUNG SYSTEM

fill the apparatus we use separate inlet and outlet tubes (Figs 1 and 5) The blood is sucked by the venous pumps into the apparatus directly from the blood-container The air, or if the system is previously filled with saline, the saline, can escape through the outlet tube In order not to spoil blood the last quantity of saline can be left in the system to mix with the blood, air bubbles if present can escape via the shunt to the venous pump of the apparatus where they mix with the oxygen in the oxygenators and do no harm When the apparatus is full of blood, the shunt in function, and no air bubbles are present in the arterial part, the apparatus is ready for use As soon as the connections with the subject are completed and the shunt is closed, the operator adjusts the venous pumps in such a way that a maximum of blood (to read from the rotameter) is sucked from the subject If suction is too weak only a part of the blood is sucked from the venae cavae On the other hand if suction is too strong the wall of the veins may be sucked into the openings of the catheters and thus close them To reduce this difficulty to a minimum we used catheters which have 3 or 4 openings When optimal suction is established the operator adjusts the arterial pumps, so that the automatic regulator comes into function only now and then Once this is done the operator has only to give general supervision to the workings of the apparatus, to watch the temperature of the outcoming blood in order to adjust the heat of the waterbath and to keep under control the flow of oxygen (preferably with 5 per cent carbon dioxide) Other than this the apparatus works automatically and reliably, in the hundreds of hours it has been in use we have had not the slightest trouble with it

Testing the capacity of the apparatus As the apparatus is meant for use in man, we had to find a way to test its real capacity *in vivo* For this purpose we used two dogs with a body weight respectively of 30 and 32 kilograms, that is about half the weight of a man Therefore we used only half of the apparatus, i.e. 3 venous pumps, 3 oxygenators, and 3 arterial pumps Under these conditions both dogs lived for 2 hours on the mechanical system The elec-

trocardiograms showed no, or very small, alterations, and when shutting off the apparatus after 2 hours, the organic heart and lungs resumed their functions immediately To determine whether the mechanical system was sufficient to maintain the life processes, a closed leather mask was tightly fitted over the mouth and nose of the animal, so that it had no chance to breathe (In our earlier experiments we sometimes clamped the trachea for the same reason) The animals showed no sign of distress during this procedure and it was obvious that it was just the same whether the mask was present or not Thus we may take it for granted that oxygenation by the mechanical system was sufficient in these experiments

Once more I would point to the fact that while in our method the complete circulation is maintained, there is no reason to believe that the functions of the organs (kidney, liver, glands of internal secretion, etc) are impaired We may assume therefore that all life processes go on materially unaltered

In these experiments the volume per minute varied between $1\frac{3}{4}$ and $2\frac{1}{4}$ liters, thus if the whole apparatus were used the volume per minute under similar conditions would reach about 4 liters, this indeed being approximately the quantity which is necessary to maintain life in man

As the experiments proved that half of the apparatus was sufficient to maintain life in dogs of 32 kilograms, we may readily believe that when the whole apparatus is used circulation will be sufficient for a normal man of about 64 kilograms bodyweight

One might ask whether we know that with our method the heart is really empty of blood In fact we do not know, it is possible of course that not all the blood is sucked away from the venae cavae, and that part of it still enters the heart cavities But this would not matter at all Our experiments just mentioned revealed that enough blood passes through the mechanical system to maintain life, and that is what we want If the artificial system is used to replace the heart or the lungs to relieve these organs temporarily, it is quite irrelevant if a fraction of the blood passes the organic heart and the lungs, the real test in such cases

is that the mechanical system be sufficient to sustain life. If, on the other hand, the artificial system is used in intracardial operations or the like, then the surgeon may, since the thorax is opened in these cases, clamp the venae cavae close to the heart to be sure that no caval blood enters the heart.

The sterilization of the apparatus. It is necessary of course that it be possible to sterilize the whole system. The 6 venous pumps are mounted on a detachable strip and can, together with their tubing, be put in a sterilizer. The 6 arterial pumps with their tubings can be sterilized by heating to 100 degrees C. in their own water baths. The rest of the glass-work and tubing and the reservoir can also be disconnected and sterilized by heat.

We are, however, looking for a more simple method of sterilization, so that the whole apparatus may be sterilized intact. Therefore experiments are in progress with very promising results. We proceeded as follows. After a general cleansing of the apparatus by perfusing it at its own power with water, a pepsine-HCl solution at 37 degrees circulates through the whole system for about 30 minutes. By this procedure the protein which might adhere to the walls is removed. Then a disinfecting solution circulates through the apparatus for some time, eventually heated to 55 or 60 degrees in the waterbath.

To control sterility, after such a procedure we filled the apparatus with a sterile bouillon solution which circulated for hours in the system. From this bouillon the bacteriologist took samples to test it on different kinds of solutions at various temperatures. In our last experiment he found that from 21 samples 17 were entirely sterile, the other 4 showed a few colonies of nonpathogenic bacteria. He estimates that not more than 1 bacterium per 30 cubic centimeters of bouillon was present. Thus this simple method of autosterilization will surely prove to be effective, as we have stronger disinfectants on our program. To be entirely on the safe side it may seem to be advisable to add penicillin to the blood in the apparatus when in the future the apparatus is used in operations on man.

Special measures. Clotting of the blood must be prevented of course. Until now we

did not apply silicon-coating to the apparatus, but, in our experiments on dogs, added an anticoagulant. We used chlorasol-pink or heparin. Both gave good results. Needless to say the necessity to make use of an anticoagulant is a weak point in any extracorporeal circulation procedure. We do not exactly know how a patient will react to a large dose of heparin and in case of extensive operations it is obvious that it may cause difficulties. The only statement I can make is that in our dogs such troubles were far less than we had expected. Especially when used in man we are of the opinion that it will be necessary to use pyrogen-free solutions in the apparatus.

SUMMARY AND CONCLUSIONS

We believe that our apparatus, from a technical standpoint, may be considered ready for a trial in man. For the surgeon there is of course still the question of the use of heparin, and perhaps other unforeseen difficulties of pure medical character may arise. However, in technical and physiological respects we are pretty sure. As to the technical performance, the apparatus did not show any failure during its long hours of use, the capacity of the pumps is such that even if one or two of both the venous or the arterial system might fail, the remaining pumps still have sufficient capacity, and if ever the whole apparatus might stop, nothing serious may occur, since the organic heart takes over its function immediately as soon as the blood is no longer sucked away from the venae cavae. If this should happen exactly at the moment the heart is opened by the surgeon, complications might arise, but this would seem to be a very special coincidence. As to the physiologic aspects, the mechanical heart maintains the whole circulation to brain, spine, liver, kidney, glands with internal secretion and so on, so that we may expect that all the functions in the organism, nervous, secretory, hormonal, etc., go on more or less normally.

We would not hesitate to use the artificial heart-lung system in a patient in whom other means had failed and there was the possibility of saving his life.

To make the apparatus as reliable as possible our first specimen is heavier and bigger

JONGBLOED MECHANICAL HEART-LUNG SYSTEM

than really necessary. With the experience gained in the construction of this apparatus we intend to build a second one of smaller overall size.

A description of a mechanical heart-lung apparatus and a method for total artificial circulation are presented. The capacity of the apparatus is sufficient for future use in operations in man.

The artificial lung is based on a quite new principle, the spiral oxygenator causes neither hemolysis nor foaming of the blood.

The possibilities for its application in cases of intracardial operations and the like in man, or as a real artificial heart or artificial lung in cases of serious, acute heart or lung affections are discussed.

ABNORMAL BLEEDING — II

Further Clinical Experience With Toluidine Blue and Protamine Sulfate

J GARROTT ALLEN, M D, F A C S, BURTON J GROSSMAN, M D, RICHARD M ELGHAMMER, M D, PETER V MOULDER, M D, CHARLES L McKEEN, M D, MARGARET SANDERSON, B S, WILLADENE EGNER, B S, and JAMES M CROSBIE, M D, Chicago, Illinois

ABNORMAL bleeding may arise from disorders of the plasma, the formed elements of the blood and the vascular wall. Hemorrhage may occur when any one of these systems is disturbed, although bleeding is frequently complex in origin and may result from disorders which directly or indirectly involve many or all factors concerned with hemostasis. It may be that the vascular factor is affected directly or indirectly in all types of abnormal bleeding.

This report comprises a series of studies carried out on a group of patients with a variety of bleeding disorders. Common to all of the patients of this group was a clotting disturbance revealed by a protamine titration (3).¹ This clotting abnormality was frequently associated with thrombocytopenia, but it also occurred in some patients whose platelet counts were normal. It was absent in others who had severe thrombocytopenia. Also associated with the increased protamine titration in some instances were petechial hemorrhages and positive Rumpel-Leede phenomena, but here again the protamine titration was increased in some patients who had no clinical evidence of vascular change. The clotting time of whole blood was often moderately prolonged, however, this change was detectable only with careful technique. The prothrombin activity was usually normal or near normal. The nature of the clotting defect revealed by the protamine titration remains in question.

From the Department of Surgery of the University of Chicago and the Argonne National Laboratory.

Done in part under U S Army Contract No. W49-007 MD 425. The views expressed are those of the authors and do not necessarily represent those of the Army.

¹Following the addition of a standard concentration of heparin to normal blood, a remarkably constant amount of protamine is required to restore clotting. (Laboratory normal for males and most females is 0.140 milligram of protamine per milliliter blood containing 0.091 milligram of heparin.)

There are certain similarities between this clotting disturbance and that produced by the injection of commercial beef heparin. However, there are certain distinct differences. (1) Resolution of this problem is difficult because many factors are involved, and because the methods of study are inaccurate and not necessarily specific. Present means for heparin identification are not suitable for human use because of the large amounts of blood required to isolate even a few micrograms of crystalline material (7). In addition, the crystalline material may vary considerably in anticoagulant potency (8), and when of poor quality, it may be difficult to identify. The inactivation of the anticoagulant activity of heparin by protamine sulfate or toluidine blue has been frequently interpreted as a biologic means for identifying heparin. Unfortunately, these reactions are shared by other biochemical compounds contained within the body. Some of these are chemically similar to heparin and some are not. Many of these compounds have some anticoagulant activity, although none is as potent as commercial heparin itself. This is further complicated by the fact that most studies have been concerned with beef heparin and that little is known of human heparin.

For these and other reasons the clotting disorder common to these patients and disclosed by the protamine titration can be considered only as resembling that produced by the injection of heparin. Whether the anticoagulant defect is heparin-like in the chemical sense remains to be seen. The term "heparinemia (?)²" was used to describe this syndrome in dogs (4). It was used generically to indicate certain similarities between the clotting defect of this syndrome and that produced by heparin in

ALLEN ET AL ABNORMAL BLEEDING—II

jection. It was interrogated because certain aspects of the problem were and still are unsettled.

METHODS OF STUDY

Coagulation studies included (1) the protamine titration (3), the normal titration end-point for humans is 0.140 milligram (protamine requirement) per milliliter of blood containing 0.091 milligram of heparin, (2) whole blood clotting time (1), for normal human blood this is 25 to 35 minutes with the technique used, (3) prothrombin activity—a one stage method with the normal being 100 per cent (10), (4) observation for clot retraction, and, (5) observation for clot lysis 6 and 24 hours after coagulation.

Studies on the formed elements of the blood included erythrocyte, leucocyte, thrombocyte, and leucocyte differential counts and hemoglobin content.

CLINICAL OBSERVATIONS

An analysis of the data obtained on these patients suggests that their hemorrhagic tendency may be advantageously classified with respect to the presence or absence of hemocytologic disorders.

Patients without evident hemocytologic disorders. This group of patients is composed primarily of women, although it has been demonstrated in 2 males who had excessive bleeding after surgical procedures. In women this clotting disturbance has been observed in some cases of menorrhagia (1) and some cases of delayed postpartum hemorrhage. In 2 of the postpartum patients, the hemorrhagic feature was serious, in 1 it was troublesome but less severe (Table I). All 3 showed a prolongation of the whole blood clotting time and an increased protamine titration. The platelet counts and prothrombin times were near normal. A marked increase of fibrinolytic activity was present in 1 patient, Case 2, but this was greatly reduced after the first toluidine blue and protamine administration. The protamine titration, when returned to normal (0.140 mgm), and maintained there for several days, remained normal. This suggests the self-limiting nature of the disorder in the postpartum group, although toluidine blue may be necessary to hasten the return to normal.

Of interest was the fact that none of these patients had petechiae or a "positive" Rumpel-Leede test, although ecchymoses occurred at the site of needle punctures.

The abstracts of the clinical courses of 2 of these patients are presented below. The menorrhagic group will be reported elsewhere (1).

CASE 1 (Table I) A 32 year old female, secundagravida, nullipara, was admitted to Chicago Lying-in Hospital, where she delivered after 9 hours of labor. A small cervical laceration was repaired with No. 6 chromic catgut sutures as were the deeper layers of the episiotomy wound. The skin was approximated with four interrupted cotton sutures.

On the ninth postpartum day, uterine bleeding occurred, for which a curettage was done and 600 milliliters of citrated blood were given. Because of the continued bleeding, an incomplete vaginal hysterectomy was performed on the following (10th) day. A 600 milliliter citrated blood transfusion was given. The uterus showed prominent lymphatic channels, no myomas and no retained placenta. Ascorbic acid and vitamin K were given daily thereafter. Bleeding continued from the lower episiotomy wound. This was temporarily controlled by three mattress sutures on the eleventh day, at which time she received 1200 milliliters of citrated blood. No bleeding occurred until the fourteenth day, when spotting was noted along the episiotomy suture line. This was resutured with one mattress suture, which controlled bleeding until the 16th day, when fresh bleeding resumed from the episiotomy site. This area was packed on the 16th day, but oozing continued and the episiotomy was resutured on the 18th day. One 700 milliliters citrated blood transfusion was given on the 16th day and 500 milliliters of blood were given as a direct transfusion on the 17th day.

On the 18th day the protamine requirement in the titration exceeded 0.200 milligram of protamine sulfate and the whole blood clotting time was 47 minutes. The platelet count was 244,000/cubic millimeter and the prothrombin activity was normal. The remaining studies were normal. One milligram of protamine sulfate per kilogram was given intramuscularly every 4 hours for 10 days, bleeding stopped within 4 hours after the initial injection and did not recur. The patient was discharged on the 29th postpartum day. The protamine titration and the clotting time were normal 12 hours after protamine therapy was instituted and remained so even after protamine was discontinued on the 26th day (10th day of protamine sulfate). The blood of the patient was examined 3 months later and found to be normal with reference to the above mentioned clotting studies.

During the hemorrhagic period (9th to 18th postpartum day), the patient received 3,600 milliliters of blood which maintained her

TABLE I—LABORATORY AND CLINICAL FINDINGS IN A GROUP OF PATIENTS WITH POSTPARTUM BLEEDING AND AN INCREASED PROTAMINE TITRATION

Patient	Age	Diagnosis	Protamine titration in mgm		Laboratory data clotting time in min		Prothrombin time %	Platelets	Therapy	Manifestations of bleeding	Clinical response and time of response
			Before therapy	After therapy	Before therapy	After therapy					
385320 (Case 1)	32	Postpartum hemorrhage	> 0	0.14	47	18	100	744,000	3.0 mgm /kgm Protamine Daily X 10	Uncontrolled vaginal bleeding which did not respond to numerous resuturing attempts blood transfusions or hysterectomy	Complete cessation of bleeding within 24 hours. No further bleeding. Rechecked at 3 months and all coagulation studies normal
418980 (Case 2)	25	Postpartum hemorrhage	0.40	0.20 (2 hr)	10	30	54	260,000	6.0 mgm /kgm toluidine blue 3.0 mgm /kgm protamine	Postpartum hemorrhage and blood transfusion reaction—profuse bleeding which slowed after perineal repair and vaginal pack. Marked fibrinolysis	Clotting time and protamine titer were decreased within 2 hours. A slight oozing around 1 pack continued
			0.20	0.14	30	30	64		6.0 mgm /kgm toluidine blue Daily X 2 3.0 mgm /kgm protamine Daily X 6	Continued slight oozing around pack	Clinical and laboratory response immediate. No further bleed.
451162 (Case 3)	26	Postpartum hemorrhage	0.16	0.14	25	18	80	180,000	6.0 mgm /kgm toluidine blue 3.0 mgm /kgm protamine	Irregular postpartum bleeding of 26 days which did not respond to dilatation and curettage. Vaginal pack was required. Oozing continued around pack	Oozing around pack slowed and stopped within a few hours
									6.0 mgm /kgm toluidine blue Daily X 5 3.0 mgm /kgm protamine Daily X 4	Pack removed with minimal bleeding	No further bleeding

erythrocyte count at 3,080,000 and her hemoglobin at 10 grams per cent. A slight febrile reaction followed the two transfusions given on the 11th postpartum day.

CASE 2 (Table I) Report of this case has been presented elsewhere (1).

CASE 3 (Table I) A 26 year old female, was delivered at the Chicago Lying-in Hospital. Bleeding was slightly in excess of normal immediately after delivery but required no transfusion. The placenta was intact. No abnormal bleeding occurred after 2 hours and the remainder of the postpartum course was uneventful. She was discharged on the 9th day on 0.0002 gram of ergotrate because of subinvolution of the uterus.

She was readmitted on the 18th postpartum day because of vaginal bleeding of 4 days' duration. On bed rest this subsided in 3 days and she was again discharged.

Two days later she was readmitted because of recurrent bleeding. On this day a dilatation and curet-

tage were performed, bleeding was excessive and the uterus was packed, but some bleeding continued through the pack for 36 hours and hysterectomy was contemplated. At this time (36 hours after packing), the whole blood clotting time was normal (25 minutes), but the protamine titration was increased to 0.160 milligram. The platelet count was 180,000 and the prothrombin activity was normal. There was no evidence of excessive fibrinolysis. She was given 6 milligrams of toluidine blue per kilogram and 3 milligrams of protamine sulfate per kilogram intravenously. Two and one half hours after administration the protamine titration was normal, as was the clotting time. At this time the uterine pack was removed and no bleeding occurred. Four milligrams of toluidine blue per kilogram was given 6 hours later. Six milligrams of toluidine blue per kilogram was administered daily after removal of the pack for 5 days and 1 milligram per kilogram protamine sulfate was given intramuscularly every 6 hours for 4 days. No further bleeding occurred. The protamine titration remained normal after the initial toluidine blue injection. She was discharged on the

9th hospital day and the 29th postpartum day. Follow-up studies have been normal to date (4 months).

Patients with hemocytologic disorders The primary diseases in the patients comprising this group were varied, but all showed severe marrow disturbances resulting from their primary disease or therapy. The protamine titrations in most cases were increased as were the whole blood clotting times. In addition, in contradistinction to those patients presented above, most of these patients had thrombocytopenia, many had petechiae as well as ecchymoses. The bleeding tendencies in these patients were complicated in addition to the increased protamine titration. In this group all three of these factors contributed to the hemorrhage. The return to normal of the titration when toluidine blue was administered lessened the patients' hemorrhagic tendency only to the extent that the factors responsible for the abnormal titration contributed to bleeding. In no case was the platelet count appreciably altered by this therapy and, so far as clinical tests show, the vascular abnormality was not improved. Hence, this antihemorrhagic therapy was incomplete in that the vascular and platelet disorders remained unchanged.

Representative case abstracts of five patients are presented below.

CASE 4 (Table II) A 7 year old male, entered the Bobs Roberts Hospital with a diagnosis of acute stem cell leukemia. Aminopterin therapy was started as a 1 milligram daily dose for 3 days. During the second 3 days the dosage was increased to 2 milligrams per day and reduced to 1 milligram on the 7th day when petechiae appeared. On the 8th and 9th days there were large ecchymoses. On the 8th day hematemesis occurred and blood was present in the stool. Aminopterin was discontinued after the seventh day.

At this time the protamine titration was 0.180 milligram, the whole blood clotting time was 45 minutes, the platelet count was 24,000 and the prothrombin activity was 100 per cent of normal. Toluidine blue, 8 milligrams per kilogram, was given intravenously on the 8th and 9th days. This was augmented by a 1 milligram per kilogram dose of intramuscular protamine twice daily during the same period. All evidence of bleeding ceased after 48 hours and no new petechiae or ecchymoses formed. Except for a 24,000 platelet count, all other clotting studies were normal 24 hours after the first injection

of toluidine blue. Eight days later the first signs of remission of the leucemic process appeared, improvement continued, and temporary remission was obtained. Clotting studies were normal and there was no bleeding in the period of remission.

CASE 5 (Table II) A 38 year old white housewife, has been observed frequently in Billings Hospital for 8 years because of abnormal bleeding. As a very young child, she bled excessively and bruised so easily that there was a family interdiction against spanking. Menstruation from its beginning at 16 years of age was so excessive and prolonged that she became acclimatized to a constant state of profound anemia, her red blood count remained in the neighborhood of 2,500,000 per cubic millimeter and the hemoglobin around 5 grams per cent. The platelet count remained on numerous occasions until 1944, cubic millimeter on numerous occasions of thrombocytopenia when more definite evidence of x-ray sterilization developed. She finally consented to x-ray sterilization, which was carried out March 24 and 25, 1944, a depth dose of 400 roentgens was given to each ovary. Vaginal bleeding, epistaxis and oral bleeding continued, and the platelet count fell and varied between 25,000 and 100,000. Because of this x-ray sterilization of the spleen (total 800 r) was given over a 10 day period in late July, 1944. The platelet count was not appreciably affected, splenectomy was advised but refused. Whether related to normal or not, the bleeding materially lessened, the red blood count and hemoglobin returned to normal levels, and the patient complained of plethora (dizziness, feeling of fullness in head, and warmth). The plethora disappeared in 1946 when severe menses resumed, although purpuric manifestations did not reappear until 6 months later, January, 1947. These bleeding manifestations continued, the period of menstrual flow increased from 10 days to 41 days. Of interest was the fact that the Rumpel-Leede test was always strongly positive, but spontaneous petechiae were absent. Ecchymoses were the only obvious manifestations of her cutaneous bleeding. Her most recent hospital admission was after 40 days of vaginal bleeding. At this time the hemoglobin was 8.0 grams per cent, the red cell count was 2,400,000, the platelet count was 40,000, the bleeding time as always was prolonged to over 20 minutes. The clotting times throughout the 8 year study were normal.

The protamine titration was first performed on this patient June 22, 1948, at which time her bleeding state was active. The titration was increased to 0.180 milligram of protamine. Seven milligrams of toluidine blue per kilogram of body weight was given intravenously, 6 hours later the titration was normal, at the end of 24 hours, bleeding had stopped. Three blood transfusions, each 500 milliliters, were given over the next 3 days (June 23 to 25). Vaginal bleeding resumed June 28, at which time the protamine titration was again increased to 0.040 milligram above normal. On June 29, 7 milligrams of toluidine blue per kilogram of body weight were again given and

TABLE II—SUMMARY OF LABORATORY AND CLINICAL DATA OF BLEEDING PATIENTS WITH AN INCREASED PROTAMINE TITRATION

Patient	Age and sex	Diagnosis	Laboratory data						Therapy	Manifestations of bleeding	Clinical response and time of response
			Protamine titration in mgm		Clotting time in min		Prothrombin time %	Platelets per cu mm			
			Before therapy	After therapy	Before therapy	After therapy

followed by one whole blood transfusion. Bleeding again stopped. The same toluidine blue dose was again given June 30 and July 1. The protamine titration promptly returned to normal until July 4, when it was increased to 0.200 milligram July 5, with bleeding continuing, 7 milligrams of toluidine blue per kilogram of body weight and 500 cubic centimeters of blood were given, and bleeding stopped. Splenectomy was performed on July 6. The immediate preoperative protamine titration was normal, 4 hours after operation it increased to 0.180 milligram and 7 milligrams of toluidine blue per kilogram of body weight were given later in the day. The following day the titration was decreased to 0.160 milligram but, because the platelet count was normal (340,000), no more dye was given. The titration returned to normal on July 9, the third postoperative day. Abnormal bleeding did not recur, the Rumpel-Leede test returned to normal, the bleeding time was 3 minutes. These tests, including the protamine titration, have continued normal to date (7 months).

The diagnosis of idiopathic thrombocytopenic purpura in this patient was based upon thrombocytopenia and marrow studies in which no platelets were seen in spite of numerous megakaryocytes. The fact that the history of bleeding antedated the thrombocytopenia by so many years raises the question as to the basic disturbance. An agnogenic clotting defect was described in this patient 8 years ago (5). This was demonstrated on recalcification of plasma and the addition of extreme dilutions of thromboplastin. It may be that the original plasma clotting defect and the thrombocytopenia which developed later were independent phenomena or that there were a cause and effect relationship not otherwise understood.

CASE 6 (Table IV) This patient suffered from idiopathic thrombocytopenic purpura without any increase in the protamine titration and did not respond to toluidine blue therapy. This patient was a 28 year old male who was admitted to Billings Hospital. He was troubled with epistaxis and cutaneous petechial hemorrhages most marked over the legs. The spleen was not palpable. Laboratory findings showed no anemia but thrombocytopenia was present, varying from 35,000 to 100,000 platelets per cubic millimeter. The leucocyte count was 8,500, the differential count was normal. The bleeding time was moderately prolonged up to 24 minutes but the whole blood clotting time was normal. The protamine titrations were normal on 5 occasions. The sternal marrow disclosed no free platelets, although the megakaryocytes were normal in number. The diagnosis of Werlhof's disease was made.

The patient was given toluidine blue on 4 occasions with no effect on petechiae formation as measured by the Rumpel-Leede test before and 12 hours after dye administration. Splenectomy was performed and the platelet count responded rapidly, reaching 200,000 within 24 hours. The Rumpel-Leede test was negative when tested 4 days after splenectomy. One week after operation the sternal marrow contained large numbers of platelets in and around the megakaryocytes (normal). The patient is asymptomatic with a normal platelet count 5 months after splenectomy.

CASE 7 (Table II) A 28 year old white female, was admitted to Billings Hospital September 30, 1948, with the chief complaints of easy bruising and intermittent vaginal bleeding for 5 weeks.

She stated that she had been well until August, 1948, when she noted the spontaneous appearance of small red spots and bruises on her skin. Her menstrual period at this time was exceptionally heavy. The flow continued and she was admitted to another hospital September 10. There she received six blood transfusions with no effect on her bleeding. Her protamine titration at this time was increased to 0.180 milligram of protamine. She was given 4.5 milligrams per kilogram of body weight of protamine sulfate and 24 hours later she was only spotting. She was then given 6 milligrams per kilogram of body weight of toluidine blue and the vaginal bleeding stopped. The protamine titration returned to normal. Clotting times were not done at this time. She continued to show petechiae. The stools remained positive for blood. On September 21, 5 days after discontinuing toluidine blue therapy, she began bleeding vaginally and continued until admitted to Billings Hospital on September 30. Numerous hemorrhages were present in the eye grounds and in the mucous membranes of the mouth. There was no nasal or oral bleeding.

The urine contained many red blood cells. The erythrocyte count was 2,020,000 per cubic millimeter. The hemoglobin was 8.5 grams per cent. The leucocyte count was 1,900 per cubic millimeter. The differential leucocyte count showed 76 per cent small lymphocytes and 18 per cent neutrophils. Normoblasts were present in the peripheral blood. The thrombocyte count was 15,000 per cubic millimeter. Prothrombin activity was normal, the protamine titration was 0.180 milligram and the whole blood clotting time was 50 minutes. The bone marrow showed absence of platelets and megakaryocytes.

On the evening of admission she was given 4.5 milligrams per kilogram body weight of protamine sulfate intravenously. The vaginal flow stopped within 12 hours and the protamine titration returned to normal. A single daily dose of 2.5 milligrams per kilogram of protamine sulfate was given for 5 days. The bleeding was controlled and the clotting studies remained normal until the fifth day when the titration suddenly increased to 0.180 milligram and the clotting time increased to 53 minutes. On the sixth day vaginal bleeding resumed and new ecchymoses

ALLEN ET AL ABNORMAL BLEEDING—II

appeared. She refused toluidine blue because of nausea. The following day (7th hospital day), she complained of severe headache and nuchal rigidity was demonstrated. She became comatose several hours later, and, despite whole blood transfusions, protamine sulfate, toluidine blue, and hypertonic glucose, she became progressively worse and died 18 hours later.

At autopsy massive intracranial hemorrhage, hemorrhagic gastroenteritis, and about 100 milliliters of free blood in the peritoneal cavity (probably from a ruptured hemorrhagic ovarian cyst) were found.

Blood drawn at the time of death showed a complete absence of fibrinogen. The patient's blood lysed normal blood clots in dilution of 1 part patient's blood to 9 parts normal blood.

CASE 8 (Table III). A 38 year old white female, had carcinoma of the breast with metastases to the ribs, spine, and pelvis. During a period of 4 months, she received repeated heavy doses of x-ray (an original 5000 r and then 2400 r to each of four involved bony areas). One month after the last dose, bleeding occurred about the mouth, especially from the lips and the tongue. There were large submucosal hematomas which threatened occlusion of the respiratory and alimentary tracts. At this time the platelet count was 10,000 per cubic millimeters and the leucocyte count was 800. Numerous blood transfusions, vitamin K, vitamin C and rutin failed to check the bleeding.

Toluidine blue (60 mgm per kgm) was given daily for 5 days. Bleeding stopped a few hours after the first injection and the hematomas began to organize. Five days after discontinuing therapy bleeding returned. She was then given on alternate days 60 milligrams per kilogram of toluidine blue and 60 milligrams per kilogram of protamine sulfate for 2 weeks. The bleeding stopped and sloughs disappeared. No further bleeding occurred to the time of her death 6 weeks later from carcinomatosis.

Table III lists a group of bleeding patients with a clinical response to toluidine blue and protamine sulfate. Laboratory data were incomplete or obtained early in the study and were not suitable for comparative purposes.

Table IV lists a group of bleeding patients with little or no clinical response. Many of these patients demonstrate the failure of therapy when the titration was normal. Some of these received inadequate therapy by present standards. Patient B R I is notable as a complete failure on routine therapy, however, the abnormal protamine titration was likewise unaffected. This failure was not understood and based on the studies of other patients, some response was expected.

Table V presents clotting studies and platelet counts on a group of patients with a variety

of disorders. The lack of association of thrombocytopenia with the protamine titration is again demonstrated. Of 11 patients with idiopathic thrombocytopenic purpura, 6 had normal protamine titrations. One patient, Case 5, with an abnormal titration, had fairly good though incomplete clinical response to toluidine blue and protamine. Four bleeding patients with normal protamine titrations had no response to therapy. Three other bleeding patients had some clinical response to therapy, but in none was the response sufficient to warrant withholding splenectomy.

Clotting factor deficiencies, as in hemophilia and prothrombin deficiency (dicumarol therapy) produce abnormalities in the titration only in so far as they prevent clot formation, the end-point. These disorders can be recognized with other tests, and they do not respond to toluidine blue and protamine therapy.

TOLUIDINE BLUE AND PROTAMINE SULFATE ADMINISTRATION

The factors responsible for the increased protamine titration and prolonged clotting time persist for varying periods of time. Successful therapy should afford adequate and continuous control of bleeding. In most instances they contribute to bleeding. In most instances the resultant defects appear to be temporarily controlled by adequate toluidine blue for 12 to 36 hours. The action of protamine sulfate was much shorter, probably less than 2 hours, and was less efficient than toluidine blue in patients whose hemorrhagic disease was complicated by other blood disorders. In the profusely bleeding patient the simultaneous administration of protamine sulfate with toluidine blue was used to take advantage of the faster initial action of protamine.

The amount of toluidine blue required to control bleeding and to restore the protamine titration to normal varied considerably in different patients. The extent to which the protamine titration was increased did not prove indicative of the toluidine blue requirement. However, a return to normal of the titration paralleled clinical improvement from the standpoint of hemorrhage in most patients.

The following therapeutic regimen is currently employed. During the first 3 days, a

SURGERY, GYNECOLOGY AND OBSTETRICS

TABLE III.—THERAPEUTIC AND CLINICAL DATA ON A FURTHER GROUP OF PATIENTS

Patient	Age and sex	Diagnosis	Therapy	Manifestations of bleeding	Clinical response
L.A.U.	2½—F	Acute monocytic leucemia	30 mgm./kgm. toluidine blue 20 mgm./kgm. toluidine blue Daily X 7	Oral, lip, gum, and cheek bleeding which did not respond to blood transfusions, vitamins C and K or rutin. Skin petechiae	Bleeding about the mouth stopped within a few hours. No new petechiae. Repair of ulcerations took 10 days
L.U.S.	49—F	Acute myelogenous leucemia	10 to 30 mgm./kgm. (varying dosage) toluidine blue Daily X 4	Oral bleeding making basin under chin necessary. Did not respond to blood transfusions, vitamins C and K, rutin or calcium gluconate	Bleeding cleared within 1 to 3 hours after 30 mgm./kgm. of toluidine blue. Lower doses allowed recurrences which immediately responded to the 30 mgm./kgm. dose
I.P.D.	5—F	Acute stem cell leucemia	25 mgm./kgm. toluidine blue Daily X 2	Bleeding from mouth, nose and eyes. Hematuria	Diminution of bleeding from eyes, nose and mouth. No effect on hematuria. Note low dose and short period of therapy
A.L.R.	23—M	Acute lymphatic leucemia	60 mgm./kgm. toluidine blue	Severe oral bleeding	Bleeding stopped 3 hours after single dose of toluidine blue. Pt. died in 3 days. Autopsy showed no hemorrhage
M.S. Case 8	38—F	Metastatic breast carcinoma. Irradiation 5000 r to skull ribs 2400 r to pelvis and lumbar spine	60 mgm./kgm. toluidine blue Daily X 5 No therapy—5 days 60 mgm./kgm. toluidine blue and protamine, alternate days X 5	Bleeding from gums, cheeks and tongue with massive submucosal hemorrhages threatening to close off respiratory and alimentary tracts. Bleeding of gums and cheeks recurred after 5 days of no therapy	Bleeding controlled within 2 days and ulcerations cleared within 4 days of initial therapy. Bleeding cleared within 2 days of second period of therapy
P.E.R.	27—F	Chronic pyelonephritis and uremia	60 mgm./kgm. toluidine blue	Vaginal bleeding and pressure cuff on arm produced petechiae	Vaginal bleeding stopped within 12 hours. Pressure cuff negative. No further bleeding
J.A.R.	34—M	Chronic glomerulonephritis and uremia	45 mgm./kgm. toluidine blue	Severe nasal bleeding	Nasal bleeding stopped within 24 hours. Single dose of dye. Excretion was slow
C.H.R.	41—F	Idiopathic thrombocytopenia purpura (Werlhof's disease)	25 mgm./kgm. toluidine blue every other day X 6 Single dose 1 wk. later	Oral bleeding of 8 months' duration. Many petechiae over extremities. Recurrence while off therapy. Refused treatment, died of intracranial hemorrhage	Oral bleeding stopped after each period of therapy. No new petechiae appeared
H.O.L.	10—F	Idiopathic thrombocytopenia purpura (Werlhof's disease)	30 mgm./kgm. toluidine blue Daily X 4	Spontaneous petechiae. Bleeding from gums	Gum bleeding stopped and spontaneous petechiae decreased
O.A.K.	22—F	Idiopathic thrombocytopenia purpura (Werlhof's disease)	20 mgm./kgm. toluidine blue irregularly	(Postsplenectomy) Showers of petechiae. No change with transfusions. Menorrhagia requiring hysterectomy	At various intervals there was suppression of petechiae formation after toluidine blue therapy in the presence of a decreasing platelet count. This low dosage failed to alter menstrual flow

daily intravenous dose of toluidine blue of 7 to 10 milligrams per kilogram of body weight is given regardless of the clinical response. If bleeding is not controlled, this dosage is continued for a total of 6 days. If after the third day the titration has returned to normal, the dosage is cut in half and this reduced dose is given daily on the fourth, fifth, and sixth days. Thereafter, it is administered when the protamine titration increases. This dosage schedule is followed in both children and adults.

Toluidine blue was prepared from the powder as a 1 gram per cent aqueous solution and was sterilized by Seitz filtration. This procedure served not only to sterilize but also to remove particulate matter. It was not auto-

claved. The amount required for each patient was pipetted into 500 milliliters of normal saline and was administered intravenously over a period of 2 to 3 hours.

Protamine sulfate was administered intravenously in 200 to 300 milliliters of normal saline over a period of not less than 40 minutes, because some anaphylactoid reaction may occur with rapid administration.

Reaction to toluidine blue thus far has been limited to brief periods of nausea and vomiting in about 15 per cent of our patients. Patients who developed these symptoms on one occasion frequently failed to have them on subsequent doses and vice versa. Protamine sulfate produced occasional headache and flushing

stances which are more physiologic than toluidine blue may be equally effective, such as gelatin (1)

DISCUSSION

With the data herein and the data of Volkert

Intramuscular protamine produced some local pain, similar to that seen on intramuscular administration of free penicillin. These doses do not relate to the therapeutic control of hemorrhage from overheparinization. Current studies indicate that other sub-

stances which are more physiologic than toluidine blue may be equally effective, such as gelatin (1)

DISCUSSION

In connection with the data herein presented, the work of Astrup and Volkert (11,

prothrombin)

is of interest. They have demonstrated an increased antithrombin titer in 11 of 26 patients with acute leucemia and in certain other cases. Minot and Denny reported a similar finding in 1 case of splenomyelogenous leuce-

mia. Castex more recently reported on 5 patients with "pseudohemophilia" who had prolonged clotting times, which were shortened but not always returned to normal when protamine sulfate was given.

The bloods of these patients are much more susceptible than normal to the effect of added heparin (2). This decreased tolerance is due primarily to the decreased thromboplastin associated with thrombocytopenia, as indicated by Howell (9) in 1917. However, bloods with reduced prothrombin activity are also more sensitive to the effects of added heparin (1). The protamine titration has been made sufficiently insensitive so that the effects of moderate prothrombin deficiency, heparinization as therapeutically employed, and thrombocytopenia were not in themselves capable of increasing the titration in otherwise normal blood.

The clinical response of these patients to toluidine blue and protamine sulfate does not necessarily imply that these agents are reacting with human heparin. Both of these agents are basic compounds containing amino groups and are capable of reacting with other compounds, many of which are normal body constituents, and some of which are not even heparin-like.

The therapeutic response appeared to be limited to the extent that this clotting defect contributed to the over-all hemorrhagic picture. Good and apparently permanent correction of the hemorrhagic state occurred in the patients listed in Table I. In this group the only detectable abnormalities were the increased protamine titration and the prolonged whole blood clotting time, except for fibrinolysis and moderate prothrombin deficiency as shown in Case 2. Temporary and slower responses occurred in the complicated hemorrhagic states listed in Tables II and III. In these patients, when ulcerations were present, the response was slow and often incomplete, this, presumably, was due to local infection, thrombocytopenia, vascular injury, and continued trauma.

Aminopterin in excessive amounts produces an ulcerative and hemorrhagic enteritis in the normal animal (1). This intestinal bleeding, like that of ulcerative colitis, is primarily local in origin, and neither of these drugs

ALLEN ET AL ABNORMAL BLEEDING—II

sponds to toluidine blue Aminopterin therapy also increases the protamine titration and usually prolongs the whole blood clotting time in the normal dog, this process is reversible with toluidine blue

The prolonged clotting time, increased protamine titration, thrombocytopenia and vascular defect in leucemia, and perhaps in certain other disorders, are probably dependent upon a common defect(s), the nature of which is not known

The vascular disturbance was probably the most important single defect in the patients listed in Tables II, III, and IV Petechiae as well as ecchymoses were prominent features in most of these hemorrhagic disorders While the vascular disorder may be exaggerated by changes in the clotting mechanism, it is probably independent of the prolonged clotting time, because hemophilia and severe prothrombin deficiency with lengthened clotting times do not characteristically produce petechiae

In a previous report (2) the fact that subcutaneous extravasation of blood was lessened in some cases led us to the erroneous conclusion that toluidine blue improved the vascular defect Any improvement in spontaneous petechiae formation appears due to changes in the clotting mechanism and not in the vascular wall Consequently, hemorrhage from vascular defects can be expected to occur and may be disastrous in the case of intracranial hemorrhage, even though toluidine blue has been given and the clotting defects returned to normal

Toluidine blue and protamine sulfate therapy proved to be of definite value in properly selected cases In a few instances it may have prolonged the life of the patient In others it gave palliative relief and lessened the amount of nursing attention required Its use in improperly studied patients will not only lead to poor clinical results, but may cause withholding from the patient other forms of indicated therapy that might be life-saving This is es-

pecially true in idiopathic thrombocytopenic purpura where splenectomy is the treatment of choice and these agents are only of value in the occasional patient

SUMMARY

1 A clotting defect is described which is similar but not identical with that produced by the intravenous injection of commercial beef heparin It is characterized by an increased protamine titration

2 The clotting defect was found in frequent association with thrombocytopenia and vascular disorders, but these associations apparently were not ones of cause and effect

3 The defect was found in a variety of diseases, many of which were severe disorders of the hematopoietic system It also occurred when no hemocytologic or coagulation disorder could be recognized

4 The defect usually responded to toluidine blue and protamine sulfate administration Clinical bleeding was influenced only to a degree commensurate with the importance of the plasma defect in the overall picture

5 The methods of administering toluidine blue and protamine sulfate are presented

EXTENSION OF PRIMARY NEOPLASMS OF BONE TO BONE MARROW

JACKSON E UPSHAW, M D, JOHN R McDONALD, M D, and
RALPH K GHORMLEY, M D, F A C S, Rochester, Minnesota

GROSS, in 1879, in his classical paper on bone sarcomas said, "From a practical point of view, it should be remembered that the medulla may be affected not only at the immediate seat of the tumor but at some distance beyond. When it is remembered that not only the soft parts and corresponding portion of the medulla of the bone around which the tumor is seated are liable to be invaded by the morbid product, but that nodules of sarcomatous tissue may exist in the medullary canal at some distance from the original growth, the line of practice to be followed in the periosteal sarcomas is to amputate as far as possible from the seat of the disease as may be consistent with the patient's safety." Since this statement by Gross, many other authors have reported the observance of medullary extension from various types of primary osseous neoplasms and some have taken note of this medullary extension in their discussions of the treatment of bone tumors. However, a search of the literature revealed no evidence of a primary study of the characteristics of extension to bone marrow as displayed by the various individual neoplasms of this problem and also the relationship of medullary extension to prognosis, diagnosis, and treatment in various primary tumors of bone.

MATERIALS AND METHODS

The following primary neoplasms of bone were studied: osteogenic sarcomas, Ewing's tumors, and primary chondrosarcomas. The myeloma series of bone neoplasms was not

Judgment of a thesis submitted by Dr. J. E. Upshaw to the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Orthopedic Surgery.

studied because it is well known that a diffuse involvement of the bone marrow is usually present and also because of the lack of proper material for study since amputation is rarely performed in these cases. Study of the vascular neoplasms of bones was confined to Ewing's tumor or malignant hemangioendothelioma of bone (Broders' classification). Although periosteal fibrosarcomas are known to invade the medullary cavity secondarily, they are not a primary neoplasm of bone and were not included in this study. The so-called endosteal fibrosarcomas have been classified as fibroblastic types of osteogenic sarcoma and will be discussed under this heading. The controversial malignant giant-cell sarcoma was not studied. No case of liposarcoma, reticulum-cell sarcoma, lymphosarcoma, erythroblastoma, chloroma, or adamantinoma was included either because of its rarity or obvious behavior as regards bone marrow extension. Metastatic lesions of bone were not considered.

The tumors selected for study were located in the long bones of the extremity. Material was obtained from extremities amputated prior to death in all cases. The basis for selection was that the tumor be located in a long bone and that the entire extent of the amputated specimen had been suitably preserved. Unfortunately, many specimens had been ruined for purposes of this study by the distal to the lesion in order to conserve storage space, or by the longitudinal sectioning of the bone which had allowed disintegration of the bone marrow. The actual location of the tumor in the long bone, site of amputation, period of survival, grade of malignancy, or in the cases of osteogenic sarcoma, the predominant cell type, were not factors considered in the selection of specimens but were considered as the study progressed. Our study concerned

Fig 1 Appearance of osteogenic sarcoma, fibroblastic type. New bone formation is not seen in this section but was present in other areas of the tumor (hematoxylin and eosin, $\times 160$)

Fig 2 Osteogenic sarcoma, chondroblastic type. The predominance of cartilage cells and hyaline matrix with new bone formation is characteristic of the chondroblastic type of osteogenic sarcoma (hematoxylin and eosin, $\times 80$)

gross and microscopic examinations of the bone marrow in specimens available in 50 cases of osteogenic sarcoma, 20 of Ewing's tumor, and 5 of primary chondrosarcoma. In each, the soft tissue was dissected from the bone containing the lesion and the limits of cortical involvement as seen grossly were measured carefully and recorded. The remainder of the bone was then examined for evidence of medullary extension past the confines of the cortical involvement. The gross features indicating involvement of the bone marrow were noted and the amount of medullary extension as seen grossly past the confines of cortical involvement were measured carefully and recorded.

Specimens were taken from the bone marrow for microscopic study at regular short intervals throughout the length of the bone containing the lesion, and the location of each specimen with regard to the bone and to the gross confines of the cortical and medullary lesion was noted. Slides were made from these specimens and these were examined. The

limits of medullary involvement were determined by microscopic study. Slides of the main lesion also were examined and the type of neoplasm and grade of malignancy were established carefully. Only Ewing's tumors were not graded.

Osteogenic sarcomas were divided into the subtypes of fibroblastic, chondroblastic, or osteoblastic on the basis of the predominant cell appearing in the lesion. In most cases all three types of cells could be demonstrated, but in every instance, one of the three types of cells was predominant and determined the type of osteogenic sarcoma. While the basis for classification of the fibroblastic (Fig 1) and chondroblastic (Fig 2) groups is evident, some explanation may be due in regard to the cases placed in the osteoblastic (Fig 3) group. The osteoblastic group was characterized by a histologic picture showing myriads of osteoblasts, new bone spicules, an osteomucoid or osteoid matrix, and anastomosing trabeculae of well formed bone, the picture predominantly was that of osteoblastic or bone-forming

Fig 3 Osteoblastic type of osteogenic sarcoma (hematoxylin and eosin, $\times 310$)

activity This classification is not original with us, having first been described in 1943 by MacDonald and Budd, and prior to these authors' paper, Simmons made a similar classification of the osteogenic sarcomas, in which he divided them into fibroblastic, chondroblastic, and anaplastic varieties. The reasons for the division of the osteogenic sarcomas into these three predominant cell types was to see whether the characteristics of medullary extension differed in the three types. That there is a definite difference in the prognosis in the osteosarcomas of various cell types and that osteoblastic or "osteosarcoma" described by MacDonald and Budd has the worst prognosis, had been well established by these authors before our study was begun.

In an attempt to determine whether or not there was any correlation between the location of the primary lesion and its tendency toward medullary extension, the amounts of medullary extension exhibited by tumors located in the lower part of the tibia or fibula, upper part of the tibia or fibula, lower part of the femur, upper part of the femur, lower part of the

radius or ulna, upper part of the radius or ulna, lower part of the humerus, and upper part of the humerus were compared for each of these bones.

The grade of malignancy was compared with the amount or extent of medullary extension in each of the cases of osteogenic sarcoma and chondrosarcoma in order to determine whether there was any relation between the grade of malignancy and the tendency toward bone marrow invasion. Ewing's tumors as said previously were not graded.

The limits of medullary involvement as seen on the preoperative roentgenograms were measured as accurately as possible and compared to the amount of extension found by gross and microscopic study of the medullary cavity of the specimen. The roentgenograms had been discarded in some of the earlier cases so that this comparison was not entirely complete but fortunately could be made in the majority of the cases.

Follow-up data were obtained in most of the cases. The following facts were ascertained as completely as possible for each patient: period of survival after amputation, if the patient was deceased, the date and cause of death were obtained, if he was living, evidence indicative of metastasis was sought. After these facts were obtained, an attempt was made to correlate neoplastic medullary extension with survival rate in each of the types and subtypes of neoplasm studied. The end results obtained in cases in which amputation had been performed across the bone containing the lesion were compared to the end results in cases in which the extremity had been removed by disarticulation of the joint or amputation across the bone proximal to the bone containing the lesion; this comparison was made in the cases of osteogenic sarcoma, Ewing's tumor, and chondrosarcoma, respectively.

The final portion of this work consisted of a statistical study of a separate group of cases of osteogenic sarcoma in an attempt to determine whether some of the observations made in the 50 cases of osteogenic sarcoma selected for the primary study were statistically significant. In the original cases of osteogenic sarcoma studied, it was found that when am-

putation had been carried out through the next higher bone or joint above the bone containing the lesion a higher percentage of patients survived for 5 years than did the group in which amputation was across the bone containing the lesion. Accordingly, it was decided to determine whether or not a larger series of cases would give similar results. The records in all cases of osteogenic sarcoma encountered at the Mayo Clinic between the years 1910 and 1935 were examined and all cases satisfying the following criteria were chosen for study. The lesion had been located in the humerus, radius, ulna, femur, tibia, or fibula, treatment had been amputation of the extremity, and finally complete follow-up history was available. Cases in which metastatic lesions were known to be present before operation were excluded. Ninety-five cases were found to satisfy these conditions, 7 of which had been included in the primary study. The remaining 88 cases were divided according to whether amputation had been by transection through the bone containing the lesion or by disarticulation of the proximal joint or amputation through the bone proximal to the bone containing the lesion. The survival rates in these two groups of cases were then compared.

FINDINGS

The gross appearance of the neoplastic involvement of the medullary cavity was similar to that of the principal lesions in almost all cases. For example, in the chondroblastic types of osteogenic sarcoma, the medullary lesion was of an osteocartilaginous nature. The variations in gross appearance of these tumors has been described at length in several textbooks and our observations corresponded with these previous descriptions. In the osteogenic sarcoma the entire circumference of the bone marrow was usually grossly involved at the point of the principal or cortical lesion, while as one progressed away from this point, medullary extension, if it occurred, tended to be along one wall or segment of the circumference of the medullary canal. The medullary extension occurring in the fibroblastic type of osteogenic sarcoma was particularly likely to spread in this manner, a small tongue-like projection being seen along one wall for several inches in

some cases. In the osteogenic sarcomas gross medullary extension was usually easy to see if it occurred, the neoplastic tissue being sharply delineated from the normal bone marrow. Medullary extension seen in Ewing's tumors was diffuse, involving the entire diameter of the medullary canal as it progressed away from the main lesion. The extension of Ewing's tumor was always of a soft, vascular nature without definite borders, and the extent of medullary involvement was difficult to determine grossly as tumor tissue faded indefinitely into normal bone marrow. The primary chondrosarcomas observed failed to exhibit any medullary extension that could be discerned by gross or microscopic examination. In all the cases studied regardless of type, the cartilaginous epiphyseal plate was noted to present an effective barrier to neoplastic extension, erosion and extension through this structure being seen only infrequently.

The microscopic appearance of neoplastic extension was the same as that of the main lesion, even the smallest microscopic projections usually exhibited the morphologic and cellular characteristics of the principal lesion. A tendency for the neoplastic cells to extend along one segment of the endosteal surface of the cortex was noted in the osteogenic sarcoma on microscopic, just as in gross, examination. In these cases, a search for malignant cells made about the periphery or circumference of the bone marrow yielded much better results than a search of the central portion, as extension was rarely seen in the central area without finding it at the periphery of the bone marrow next to the cortex for an even greater distance away from the principal lesion. In Ewing's tumor, medullary extension, being of a diffuse character, was likely to be seen all through or in any part of a cross section of the bone marrow. Invasion of, and extension along, the haversian canals in the cortex was noted in many instances, particularly in Ewing's tumors, but in no case was extension in a haversian canal found to exceed medullary extension in distance from the principal lesion. Some tendency for the lesion to extend along the outside of blood vessels was noted, particularly in the fibroblastic type of osteogenic sarcoma. In some instances plugs of tumor

Fig 4 Osteoblastic type of osteogenic sarcoma of the lower part of the femur with roentgenologic evidence of medullary involvement extending only to the midshaft

tissue were seen inside blood vessels in the bone marrow and accounted for one of the sources of distant metastasis found in primary sarcoma of bone. No barrier inhibiting medullary extension, such as a fibrous wall or capsule, was found in any specimen studied.

In all cases studied regardless of type or subtype, direct extension was responsible for medullary involvement. In no cases could a defect in the continuity of the medullary neoplastic progression away from the principal

lesion be definitely established either by gross or microscopic examination of the bone marrow.

In regard to the actual amount of extension (Table I) one-fifth of the osteogenic sarcomas studied revealed pronounced extension in the bone marrow varying from 3 inches (7.6 cm) past the limits of the cortical lesion to an involvement of the entire shaft. In another fifth of the cases extension of 1 to 3 inches (2.5 to 7.6 cm) was present and in the remaining three-fifths no medullary extension could be demonstrated. On microscopic examination medullary extension of 3 inches or more past any evidence of the lesion as seen grossly was found in 18 per cent of cases. Of the osteogenic sarcomas (Table II) the osteoblastic type showed the greatest tendency, the fibroblastic type the next to greatest, and the chondroblastic type the least tendency to medullary extension. Ewing's tumors displayed a greater tendency to extension to the bone marrow than either the osteogenic sarcomas or chondrosarcomas. Forty-five per cent of Ewing's tumors extended 3 inches or more past the cortical lesion, in 6 cases (two-thirds of this group or 30 per cent of the total group) the entire medullary cavity was involved. In 30 per cent of the cases of Ewing's tumor extension for 1 to 3 inches had occurred, and in the remaining 25 per cent, no extension was found. No extension was found past the limits of gross cortical involvement in any of the cases of primary chondrosarcoma studied.

The actual position of the main lesion in the bone was found to be of no particular value in

predicting whether or not medullary extension would occur. However, in the osteogenic sarcomas, the incidence of extension up the medullary cavity from lesions of the lower part of the femur was greater than the incidence of spread down the medullary canal from lesions located in the upper part of the tibia. The reason for this cannot be explained.

In the osteogenic sarcoma group the greatest amount of medullary extension was found in the higher grades of malignancy. Medullary extension of 3 inches or more was found in 25 per cent of lesions of grade 3 malignancy and in 29.3 per cent of the lesions of grade 4, but extension was less than 3 inches in all cases in which lesions of grade 1 and grade 2 were present. This was an expected finding in view of the greater invasive tendency and rate of mitosis exhibited by higher grades of malignancy. However, the grade of malignancy made no difference in the amount of extension in the chondrosarcoma group, none being found regardless of grade. Ewing's tumors were not graded.

The results obtained in the comparisons made between the amount of medullary extension evident on the preoperative roentgenograms as against the amount of medullary extension actually found by gross and microscopic study of the amputated extremities are given in Table III. The distance by which microscopic extension exceeded roentgenologic evidence of medullary involvement was recorded in each of the cases showing this difference and varied from 1 inch (2.5 cm) to an involvement of the entire shaft above the lesion as seen roentgenologically (Figs 4 and 5).

Fig 5 Medullary material removed from the femur shown in Figure 4. This section was from the intertrochanteric region and shows that the sarcoma has extended throughout the medullary cavity of the involved femur (hematoxylin and eosin, $\times 120$).

Survival periods following the date of amputation have been compared with the amount of medullary extension found on gross and microscopic examination. These results are given in Table IV. Those cases in which adequate follow-up data could not be obtained or in which the postoperative period was less than 3 years at the time of this study were excluded. The patient who was free from clinical or roentgenologic evidence of metastasis or recurrence of the lesion in the stump was classed as well. Data on the primary chondrosarcomas are not included in Table IV. Of the 5 patients studied, none had any medullary extension, 1 patient was considered cured, 1 died 1 year after operation, 2 were living and well but the postoperative period was less than 3 years, and 1 patient could not be traced.

The survival rates in cases in which amputation was carried out through the bone containing the lesion were compared with those in cases in which disarticulation or amputation through the bone proximal to the bone con-

taining the lesion was performed. The results are shown in Table V for the entire series of cases and in Table VI for the cases in which the various predominant cell types of osteogenic sarcoma were present. Patients were listed as cured who were living and well 5 years from the date of amputation and who had no clinical or roentgenologic evidence of metastasis. Not evident in the tables is the fact that of 6 patients who underwent disarticulation or hemipelvectomy for osteogenic sarcoma of the femur 1 died 6 months after operation, 2 patients were considered cured, 1 being alive and well 16 years after operation and the other 7 years after operation, and the 3 remaining patients were living and well, but less than 3 years had elapsed since the date of amputation.

The results obtained from the statistical study on the 88 additional cases of osteogenic sarcoma, which were selected as described previously in this paper, are contained in Table VII.

COMMENT

The lack of evidence suggesting that multiple foci of medullary involvement might evolve by the process of embolism from a primary sarcoma located in the same bone, and the demonstration of direct extension as the means by which a primary bone sarcoma spreads in the bone marrow, was interesting. It has been established that the capillaries and blood vessels conducting blood in the bone marrow are closed structures and not in communication with the parenchyma of the bone

marrow (1, 2). Therefore, malignant cells making their way through the walls of blood vessels in the medullary cavity evidently are conducted out of the medullary cavity to some distant point of the body rather than setting up a new focus of medullary involvement in the same bone. There was no evidence to suggest that spread had occurred through the lymphatics of bone marrow in any of the cases studied. Direct extension being the method of medullary spread from a primary bone sarcoma, the actual position of the neoplasm should have little influence on the incidence or amount of medullary extension that occurs. Accordingly lesions located in either the proximal or distal end of the bone were found to spread comparable distances down or up the medullary cavity as the case might be and lesions of the shaft extended in either direction.

An interesting fact was that in 10 of the 50 cases of osteogenic sarcoma studied (an incidence of 20 per cent) medullary extension was found for 3 inches or more past any cortical evidence of the lesion. In 3 of the 10 cases medullary extension was found to the point of amputation. In these 3 cases there was no record that microscopic examination of the bone marrow had been made at the time of amputation. Medullary extension was found by microscopic means 3 inches or more past any gross evidence of medullary involvement in 18 per cent of the cases of osteogenic sarcoma. This fact indicates that gross inspection of the bone marrow for evidence of medullary extension at the point of amputa-

tion is not sufficient, and that in those cases in which amputation has been performed through the bone containing the lesion, the surgeon should insist on microscopic examination of the bone marrow before deciding that the point of amputation is high enough. As was expected, the greatest incidence of medullary spread was found in cases of Ewing's tumor, the entire medullary canal was involved in 30 per cent of the cases. Too few cases of primary chondrosarcoma in the long bones were studied to permit positive statements, but the finding of no medullary extension, either by gross or microscopic means, in the 5 cases studied, suggests that the tendency toward medullary extension is much less in this form of primary bone neoplasm than in other types. The fact that in none of the cases of osteogenic sarcoma of chondroblastic type studied was medullary extension of 3 inches or more evident, also would seem to support the contention that cartilaginous neoplasms of bone show the least tendency toward medullary extension.

In the cases of osteogenic sarcoma comparison of survival rates with the amount of medullary extension failed to reveal any significant differences in the survival periods in cases in which no medullary extension was found and in cases in which marked medullary

extension was present. This finding is of significance in that it tends to show that the incidence of distant metastasis is not increased regardless of the amount of medullary extension. Invasion of blood vessels and distant metastasis occur with about the same frequency in cases in which medullary involvement is confined to the region of the cortical lesion as in cases in which lesions have spread along the bone marrow. It was thought that the incidence of distant metastasis might be increased in cases in which medullary extension was present and be reflected in a lower survival rate in these cases. The reason for this opinion was that the lesion which extends in the medulla surrounds a larger amount of the blood vessels in the bone marrow and a larger surface area is presented for invasion of the vessels. In this study, however, the results obtained seem to indicate that if amputation is carried out proximal to the lesion, the effect of medullary extension, regardless of amount, on the survival rate is nullified.

Our study of Ewing's tumor on the contrary, revealed a significant difference in the survival rates in cases in which no medullary

extension was present from those in which medullary extension had occurred. Sixty-six per cent of the patients who did not have any medullary extension were living and well 3 years after operation and 50 per cent were considered cured by the amputation. Of the patients who had medullary extension of 3 inches or more, only 11 per cent were living and well 3 years after operation, and 11 per cent were considered cured. These results tend to show that in cases of Ewing's tumor the greater the invasive tendency, as shown by the amount of medullary spread, the poorer the prognosis. Presumably this is because of a higher incidence of blood vessel invasion with distant metastasis in the cases in which medullary extension is increased.

If the surgeon could be sure that the point of amputation was above the most proximal point of a primary bone sarcoma, then the dictum of never amputating through the bone containing the lesion unless absolutely necessary would be invalid, and the end results of transection through the bone containing the lesion and disarticulation at the joint or amputation through the bone proximal to the bone containing the lesion should not differ. The surgeon, however, is confronted by many obstacles in determining whether or not the site of amputation is proximal to the lesion, if he chooses to amputate through the bone containing the lesion rather than above it. Roentgenograms may not portray the medullary extension that is present. Gross examination

of the bone marrow at the point of amputation may give an erroneous impression as microscopic medullary extension often exceeds any medullary extension that can be seen grossly. The number of errors that are made in this determination is well demonstrated by the poorer results (Tables V and VII) found in the cases of osteogenic sarcoma in which transection was done through the bone containing the lesion than in those in which disarticulation or amputation through the bone proximal to the bone containing the lesion was done. The better results obtained by the radical amputation above the bone containing the lesion take on added significance when it is remembered that the most advanced lesions showing the most involvement of cortical and soft tissues were almost always in the group treated by amputation or disarticulation proximal to the bone containing the lesion. The better prognosis offered by amputation proximal to the bone containing the lesion, is no doubt due in part to the fact that the higher amputation increases the incidence in which plastic infiltration of soft or subperiosteal tissue. An even more important factor in the better prognosis offered by the more radical surgical procedure is believed to be the fact that amputation is certain to be above the highest medullary extension of the neoplasm. Of the 14 patients who had osteogenic sarcoma treated by transection through the bone containing the lesion and who survived less than 3 years, 3 (21 per cent) displayed microscopic evidence of medullary neoplasm at the point of amputation. The failure to find more cases of extension to the site of amputation in this group is believed due to the difficulty in demonstrating malignant changes in individual cells, or in small clusters of cells which lack the morphologic arrangement of the main lesion, in the bone marrow of specimens preserved in formalin for several years. Exact information regarding the incidence of local recurrence in the amputation stump could not be obtained, but the fact that local recurrence is known to have occurred in at least 1 of the cases in which malignant change could not be found at the proximal end of the amputated specimen tends to support the view that

malignant cells were present at the site of amputation in a higher percentage of cases than could be demonstrated in the specimens available for this study

Comparison of the end results obtained by transection through the bones containing the lesion with those obtained by higher amputation was interesting in cases of the various types of osteogenic sarcoma. The fibroblastic and chondroblastic types gave findings in keeping with the results discussed for the osteogenic sarcoma group as a whole. When amputation had been performed through the proximal bone or through the joint proximal to the lesion results were much better than when transection had been done through the bone containing the lesion. In the osteoblastic type of osteogenic sarcomas these findings did not apply. No patient survived for 3 years after operation regardless of the site of amputation. This finding is in keeping with the observations of MacDonald and Budd. These authors in 1943 published the results of a study of the 118 five year cures in cases of osteogenic sarcoma listed in the bone sarcoma registry of the American College of Surgeons. They divided these cases into fibroblastic, chondroblastic, and osteosarcoma subtypes and stated, "A comparative analysis of the cases of cured and uncured osteogenic sarcoma indicates that true osteosarcoma is an almost uniformly fatal form of neoplasm, accounting for but a fraction of the cures." Their description of the histologic features of osteosarcoma corresponds to those of the lesion called "osteoblastic type of osteogenic sarcoma" in our study. Apparently the osteoblastic type of osteogenic sarcoma invades blood vessels much sooner than the fibroblastic or chondroblastic types and metastasis has occurred before the patient comes to surgery in the majority of cases.

The percentage of 5 year survivals and patients cured was twice as great in the cases of Ewing's tumor in which transection was performed through the bone containing the lesion as in the group in which amputation was carried out proximal to the bone containing the lesion. In view of the exactly opposite results in cases of the osteogenic sarcoma, this seemed unusual. Inspection of the 6 cases in

which transection through the bone containing the lesion was performed revealed that in 4 there was medullary extension of less than 1 inch, and in 2 of more than 3 inches, in 1 of these last 2 cases medullary extension was demonstrated at the site of amputation. In 7 of the 13 cases in which the limb was amputated proximal to the bone containing the lesion, medullary extension was marked, in 6 the entire shaft was involved. In 3 cases there was medullary extension of 1 to 3 inches, and in 3 no medullary extension. The 3 patients who had no medullary extension were living and well, 10, 7, and 3 years after operation, respectively. It was observed in a previous paragraph that the prognosis was poorer in cases of Ewing's tumors with marked medullary extension than in cases with little such extension, presumably because the lesions showing the greater invasive tendency, as reflected by medullary extension, also invade the blood vessels and metastasize earlier and more often than do less invasive lesions. Probably this factor is the one responsible for the failure to obtain better results in the group of Ewing's tumors treated by removal of the extremity proximal to the bone containing the lesion than were obtained in the group treated by transection of the bone containing the lesion.

CONCLUSIONS

From this study the following conclusions were drawn

- 1 Direct extension is the usual method by which a primary bone sarcoma spreads in the bone marrow from its initial location in a long bone
- 2 Medullary extension from a primary bone sarcoma may occur without roentgenologic evidence of its presence
- 3 Neoplastic medullary involvement may be found on microscopic examination for a considerable distance past any gross evidence of medullary extension in many cases of primary bone sarcoma
- 4 Of the primary bone neoplasms studied, Ewing's tumor exhibited the greatest tendency, osteogenic sarcomas the next greatest, and primary chondrosarcomas the least, to spread in the bone marrow. In this series, 45 per cent of Ewing's tumors, 20 per cent of

osteogenic sarcomas, and none of the primary chondrosarcomas showed medullary extension for 3 inches or more past the limits of cortical involvement by the lesion

5 Of the predominant cell types of osteogenic sarcoma, the osteoblastic type exhibits the greatest tendency, the fibroblastic type the next greatest, and the chondroblastic type the least, to extend in the bone marrow

6 In osteogenic sarcoma, the higher the grade of malignancy, the greater the amount of medullary involvement that is likely to be found In this study no medullary extension was found in cases of primary chondrosarcoma regardless of grade of malignancy and no attempt was made to grade malignancy in Ewing's tumors

7 The amount of medullary extension *per se* cannot be used as a basis for prognosis in osteogenic sarcoma, while in Ewing's tumors, cases with marked medullary involvement have a distinctly worse prognosis Apparently invasion of blood vessels and metastasis is as likely to occur in cases in which osteogenic sarcomas show no spread in bone marrow as in those in which marked medullary extension occurs past the confines of the cortical lesion In Ewing's tumors, however, those which have a greater invasive tendency as reflected by increased medullary extension, are more likely to invade blood vessels early and have caused undetected metastatic lesions at the time of surgery

8 In the treatment of primary bone sarcoma by amputation, microscopic examination of the bone marrow at the point of amputation should be mandatory in every case

in which amputation is performed through the bone containing the lesion before the surgeon concludes that the amputation is proximal to the lesion The recognition of malignant cells individually or in small clusters may be very difficult, and when any doubt exists, amputation should be performed at a higher level In this study the inadequacy of roentgenologic and gross methods of examination used alone for the detection of extension in the bone marrow was illustrated in the study of the survival rates in cases of the osteogenic sarcomas Microscopic examination of the bone marrow at the site of amputation was not routine in these cases It was found that in the cases of osteogenic sarcoma in which amputation was proximal to the bone containing the lesion results were superior to those in cases in which transection was carried out through the bone containing the lesion One important cause of the poor results of amputation through the bone containing the lesion, as compared to the results of amputation above the affected bone, was failure to amputate proximal to the lesion, since the amputation occasionally was through an area of medullary extension which was undetected at the time of surgery

CEREBRAL BLOOD FLOW AND METABOLISM IN TOXEMIAS OF PREGNANCY

MILTON L McCALL, M D , F A C S , Philadelphia, Pennsylvania

IN 1945 Kety and Schmidt (12) reported the determination of cerebral blood flow in man with a technique which permitted the quantitative clinical measurement of this important physiologic function. The safety and significance of this method have since been established by studies on normal young men (14) as well as on groups of individuals with varied pathologic states (10, 11, 13, 15, 16). The development of this procedure makes it possible for the first time for the clinician to study certain phases of the dynamics of disease entities which may in some degree affect intracranial physiology. Toxemia of pregnancy is typically manifested by symptoms referable to the brain. While much has been postulated concerning the cause and mechanism of this effect, actually very little indeed is known concerning the pathologic physiology of this organ which hitherto had been inaccessible to significant study. It was therefore thought worth while to use the new method in the study of toxemia of pregnancy as well as of normal pregnant women (18).

METHOD

The method is based upon the fact that if the nitrous oxide concentration be determined in arterial and cerebral venous blood for a 10 minute period from the beginning of inhalation of a low concentration of this gas, curves will be obtained as exemplified by the typical one in Figure 1. The venous concentration curve is a fairly complex function of the arterial curve and the cerebral blood flow. From these curves the cerebral blood flow can be calculated by the application of the Fick principle. This postulates, in its simplest form, that the quantity of any substance taken up in a given time by an organ from the blood which perfuses it is equal to the

total amount of substance carried to the organ by the arterial inflow less the amount removed by the venous drainage during the same period of time. It has been shown that the cerebral blood flow (CBF) can be calculated from the following formula

$$CBF = \frac{100 V_{10} S}{10 (A - V) dt}$$

Where V = Venous N₂O concentration
V₁₀ = Venous N₂O concentration at 10 minutes
A = Arterial N₂O
S = Partition coefficient of N₂O between the brain and blood

$\int_0^{10} (A - V) dt$ = The area between the arterial and the venous curves, over the ten minute period
This expresses CBF as cubic centimeters of blood flow per 100 grams of brain per minute

A gaseous mixture, consisting of 15 per cent nitrous oxide, 21 per cent oxygen, and 64 per cent nitrogen, is administered through a tightly fitting mask equipped with inspiratory and expiratory valves. For taking accurately timed arterial blood samples from artery and internal jugular vein, manifolds of 3 way stopcocks have been found to be very convenient (Fig 2). Transparent plastic tubing connects the manifold to the needle and heparin is used in the system to prevent clotting. The first needle is placed into the superior bulb of the internal jugular vein after infiltration with procaine. The second needle is placed into the femoral artery. No untoward reaction or complication has accompanied this procedure.

Five samples of blood are taken simultaneously from the arterial and venous systems at regular intervals over a period of 10 minutes during which time the nitrous oxide mixture is administered. The heparin tipped syringes are sealed and placed in cracked ice immediately. The mean arterial blood pressure is

From the Departments of Obstetrics and Gynecology of the Jefferson Medical School and Hospital and the Philadelphia General Hospital. This work has been supported by the Jefferson Obstetric and Gynecologic Research Fund

Fig 1 Typical arterial, A, and internal jugular, V, curves of nitrous oxide concentration during a 10 minute period of inhalation of 15 per cent nitrous oxide

taken directly from the femoral artery. The specimens are analyzed for nitrous oxide, oxygen, and carbon dioxide in the manometric Van Slyke apparatus (9).

From these analyses several studies of cerebral metabolism and circulation are made possible. First, as pointed out, the actual cerebral blood flow may be determined. Second, the rate and amount of oxygen utilized by the brain may also be ascertained. This is called the cerebral metabolic rate in terms of oxygen and is determined by the formula

$$\text{CMR } O_2 \text{ in c.c. of } O_2/100 \text{ gm brain/min} = \text{CBF} \times \frac{(A-V)O_2}{100}$$

A third very important function which is made possible of evaluation is the cerebral vascular resistance. A satisfactory approximation is made by the formula

$$\text{CVR in mm Hg/c.c./100 gm brain/min.} = \frac{\text{Mean arterial blood pressure}}{\text{CBF}}$$

This convenient unit represents the pressure necessary to force 1 cubic centimeter of blood per minute through 100 grams of brain.

Fourth, the respiratory quotient of the brain may be measured. It will be recalled that the RQ represents the ratio of the vol-

ume of carbon dioxide produced by a tissue to the volume of oxygen absorbed. This is ascertained by the formula

$$\frac{(V-A)CO_2}{(A-V)O_2}$$

Finally, it is possible to calculate the so-called nutritive index of the brain which is determined by the formula

$$\frac{AO_2}{(A-V)O_2}$$

This represents the ratio between the amount of oxygen offered to the brain and how much it actually uses

NORMALS

The first problem was to establish the normal values for pregnant women in each of these measurable functions of cerebral circulation and metabolism. Kety and Schmidt (14) had studied 14 normal young men. The mean values obtained in these cases were compared¹ with mean values which were determined from the study of 9 normal young women who were between 34 and 40 weeks' gestation.

TABLE I

	Normal young men	Normal pregnant women
Mean arterial blood pressure	86	90.5
Arterial oxygen in vol per cent	18	13.4
Arterial carbon dioxide in vol per cent	49	40.0
Venous oxygen in vol per cent	11.7	6.9
Venous carbon dioxide in vol per cent	55	46.2
Arteriovenous oxygen difference in vol per cent	6.3	6.5
Respiratory quotient of the brain	0.99	0.98
Cerebral blood flow	54	56
Cerebral metabolic rate in terms of oxygen	3.3	3.5
Cerebral vascular resistance	1.6	1.6
Nutritive index of the brain	2.8	2.1

It is at once obvious in Table I that the arterial and venous concentrations of oxygen as well as carbon dioxide are much lower in normal pregnant women than in normal males. The arterial oxygen content in these pregnant women close to term is 26 per cent

¹Fisher's table of *t* was used throughout this study to test the significance of difference between normal pregnant women and normal young males as well as between normal pregnant women and patients with the various types of toxemia of pregnancy. The formulae followed were

$$\text{Standard deviation } (\sigma) \text{ of difference} = \sqrt{\frac{\sum_1(d^2) + \sum_2(d^2)}{(N_1-1) + (N_2-1)}}$$

$$\text{Significance of difference } (t) = \frac{\text{Difference between means}}{\sigma \text{ of Difference}}$$

$$\sqrt{\frac{N_1 N_2}{N_1 + N_2}}$$

Fig 2 Setup for cerebral blood flow determination

lower. This is not surprising when it is recalled that it has been shown that there is normally an increased plasma volume at term (3, 5, 19, 23), the so called hydremia of pregnancy. Another factor frequently found in a group of unregistered patients who present themselves for the first time after a complication of pregnancy has developed is an abnormally lowered hemoglobin. This lessens the carrying power of the blood for oxygen and to a lesser extent for carbon dioxide. It is interesting that the arterial-venous oxygen differences $(A-V)O_2$ were approximately the same showing that during pregnancy the brain has the ability to extract the usual amount of oxygen from the blood even though the blood coming to it carries less oxygen. Thus the oxygen content of the venous blood leaving the brain is even more depleted, it being 37 per cent less than in normal males.

The lowered nutritive index of the brain of 2.1 in pregnancy compared to 2.8 in males is highly significant. This emphasizes the fact that the brain in normal pregnancy is maintaining a normal oxygen utilization in the face of a diminished oxygen supply, the

latter being the result of the relative anemia which occurs in this condition.

In the comparison between the two series of normals, the nutritive index is the only one of the major functions being studied which shows a significant difference. As seen in the table, the cerebral blood flow, the respiratory quotient, the cerebral metabolism of oxygen, and the cerebral vascular resistance give very similar values in the two groups.

TOXEMIAS OF PREGNANCY

After the establishment of normal values for pregnant women, 29 patients with toxemia of pregnancy were studied. Using the classification proposed by the American Committee of Maternal Health in 1939 there were 16 patients with hypertensive toxemia, 8 patients with pre-eclampsia, and 5 convulsive eclamptics.

Because of the importance of excluding all possible factors which might alter the cerebral state in toxic patients, an effort was made to perform the studies before any therapy whatever had been given. In order that treatment might not be delayed, the equipment necessary for the study was kept in

SURGERY, GYNECOLOGY AND OBSTETRICS

readiness at all times so that the investigation could be carried out immediately upon the patient's admission to the ward. Three of these tests were done between successive convulsions during coma. One had but one convulsion and was rational and conscious when the blood flow was performed. The only eclamptic who received any therapy before the tests were completed was still in a semicomatose state.

54
51

Cerebral blood flow. The flow of blood through the brain was found to be but little affected by the toxemias of pregnancy. The normal values obtained in the study of women afflicted with essential hypertension, in whom there was some degree of superimposed toxemia, bears out the work of Kety and his collaborators (10) on patients with essential hypertension per se that the blood flow is not affected by this condition. While the pre-eclamptics had comparatively normal blood flows, the patients with eclampsia showed a tendency toward lower values. While the flow of 51 cubic centimeters per 100 grams of brain per minute in eclampsia compared to the normal value of 56 cubic centimeters is not statistically significant in

this study, it may approach significance in a larger group of cases.

TABLE IV — THE CEREBRAL METABOLIC RATE IN TERMS OF OXYGEN

0.98
1.06

Respiratory quotient of the brain. The RQ of the brain in normal human beings is approximately unity indicating that the brain utilizes carbohydrates almost exclusively as its source of energy. In normal pregnant

women, as well as in patients with toxemia of pregnancy, there is little deviation from this value

TABLE VII —ARTERIAL-VENOUS OXYGEN DIFFERENCES AND NUTRITIVE INDEX OF THE BRAIN

	$(A-V)O_2$	$\frac{AO_2}{(A-V)O_2}$
Normal pregnant women	6.5	2.1
Hypertensive toxemia	6.3	2.2
Pre-eclampsia	6.3	2.2
Eclampsia	5.5	2.8

Arterial-venous oxygen differences $(A-V)O_2$ (Table VII) The amount of oxygen extracted by the brain per 100 cubic centimeters of blood in toxemia is not significantly different from that in normal pregnant women. However, once again there is seen a tendency toward a difference in the eclamptic group which in a larger series of cases would become increasingly significant. The patients in this group of most severe toxemias used an average of 5.5 volumes per cent of oxygen whereas the patients in the normal group used 6.5 volumes per cent.

As shown earlier, the $CMRO_2$ (amount of oxygen consumed per 100 gm of brain per minute) is lowered in eclampsia. This, of course, is the reason for the decrease in the arteriovenous oxygen difference.

The nutritive index of the brain (Table VII) The NI is approximately the same in pre-eclampsia and hypertensive toxemia as it is in the normal pregnant woman (2.1). In eclampsia there is a significant increase in this index to 2.8. This fact further emphasizes that the brain is not suffering from a lack of oxygen supply but rather from a failure to utilize the oxygen which is provided by the incoming arterial blood to a normal extent.

DISCUSSION

This study offers evidence that the physiology of the brain in normal pregnancy is much the same as that of normal young males. The only exception to this is a propensity of the brain to utilize approximately the same amount of oxygen as does the nonpregnant individual even though the arterial blood coming to it was shown to carry 26 per cent less oxygen. The decreased oxygen carrying

power of the arterial blood of pregnancy is thought to be mainly due to the physiologic hydremia.

In the toxemias of pregnancy several pertinent facts appear to be evident from this investigation. It seems significant that, aside from a slight degree of reduction in eclampsia, the blood flow is found to be constantly normal. This fact assumes importance to us inasmuch as several theories concerning the causation of eclampsia postulate that there is a greatly reduced blood flow to the brain.

Stander, in his monograph on toxemia, states that Traube and Rosenstein in 1864 first proposed that edema and actual anemia of the brain are the etiological factors in the production of eclampsia. More recently Zange-meister postulated that the development of cerebral edema caused such an increased extravascular pressure that the blood supply to the brain was greatly diminished. This "hydrops gravidarum" concept explained that the cells of the brain were inadequately nourished due to this anemia bringing about cerebral irritation and convulsions. However, the present study reveals that cerebral blood flow is maintained at normal levels which points to the conclusion that the symptoms of eclampsia cannot be explained upon the basis of generalized cerebral ischemia.

The cerebral vascular resistance is the function affected most frequently in toxemia of pregnancy. We found essential hypertension upon which toxemia was superimposed similar to that in nonpregnant patients with essential hypertension in this respect. In pre-eclampsia the resistance was quite high, but the greatest degree of cerebral vascular resistance was encountered in the presence of eclampsia.

The mechanism of this abnormality is most likely based upon a narrowing of the vessels within the brain. This might be due either to an intrinsic action within the vessel itself such as vasospasm, or to an extrinsic pressure caused by edema or increased intracranial pressure of the cerebrospinal fluid. In essential hypertension these extrinsic factors are not observed as a rule, nor are they in pre-eclampsia although generalized edema is

SURGERY, GYNECOLOGY AND OBSTETRICS

more likely to develop. In eclampsia a wet brain is not an unusual finding at autopsy although there are many cases, especially the severe so-called "dry eclamptics" which do not exhibit this abnormality. In our experience, increased spinal fluid pressure is an inconstant finding. Therefore, while any of the three mechanisms may bring about the increased cerebral vascular resistance in eclampsia, it is likely that vasospasm is the most frequent cause.

It has been recently shown by Odell, Aragon, and Pottinger that there is an increase in the cohesiveness of red cells in toxemia of pregnancy. This has been called "sludging" by Knisely and brings about a slowing of blood flow through the smaller venules as observed in the conjunctiva. Whether or not such a phenomenon could increase the resistance to blood flow in the brain is postulated. If such takes place it might be postulated that there is an immediate reflex increase in blood pressure which maintains the cerebral blood flow at a normal level.

It has been shown that partial constriction of arterial inflow to various organs may cause vasospasm and hypertension. Cushing (1, 2) showed that restriction of the blood flow to the brain causes hypertension. The work of Goldblatt upon the kidney revealed a similar cause and effect as did the work of Ogden, Hildebrand, and Page upon partial constriction of the uterine arteries in pregnant dogs. While our study shows no interference with the blood flow to the brain during the disease, it is as yet conjectural as to whether or not there is a preliminary transient lessened blood flow to the brain, kidneys, or placenta which brings about the increase in blood pressure and vasospasm. A generalized capillary spasm over the body has been suggested by the work of Hinselmann, of Haselhorst, and of others.

Halbertsma, in 1884, postulated that a deficiency of oxygen is the immediate cause of eclampsia. Since then numerous writers have regarded a disturbance in oxidation as the exciting cause. Stander states, "Whatever theory ultimately explains the etiology of eclampsia will have to take decreased or deficient oxidation into account." In our tests

the oxygen consumption of the depressed in eclampsia but was in the nonconvulsive toxemias therefore, seems to correlate the with the mental clearness of the amount of oxygen carried in the is approximately the same in toxemia as it is in normal pregnancy. Conceivable that the brain of the has lost the ability to utilize oxygen. With cerebral blood flow unaltered significant degree, this points to hood that there is some inherent disturbance in the brain cells themselves rendering less capable of using oxygen. It is hoped that this report will stimulate the further investigations which are necessary for a more complete understanding of the pathologic physiology of the brain in the presence of the toxemias of pregnancy.

SUMMARY

- 1 By a recently devised method, the cerebral blood flow and related circulatory and metabolic functions of the brain have been studied for the first time in normal pregnancy as well as in patients with toxemia of pregnancy.
- 2 Normal pregnant women were found to have a lowered oxygen content of the arterial blood but were able to show the same amount of oxygen utilization by the brain as were normal nonpregnant individuals whose arterial blood carried 26 per cent more oxygen.
- 3 The cerebral blood flow was found to be normal in all toxemias of pregnancy.
- 4 The cerebral vascular resistance was significantly increased in each type of toxemia, the greatest degree being present in eclampsia.
- 5 The oxygen consumption of the brain was significantly decreased in eclampsia but was not impaired in the nonconvulsive toxemias.
- 6 The possible implications of these findings are briefly discussed.

STUDIES ON THE EFFECTS OF CONCOMITANT VENOUS LIGATION IN ACUTE ARTERIAL OCCLUSION

M L CULLEN, M D, L G STEPPACHER, M D, BENJAMIN GREENSPAN, M D,
H E MILLIKEN, Jr, M D, G W MOORE, M D, and G C MORRIS, Jr, M D,
Philadelphia, Pennsylvania

SINCE Sir George Makins, on the basis of observations made during the Boer War, postulated the theory that concomitant vein ligation at the time of ligation of a major artery of an extremity lowered the incidence of gangrene, numerous contradictory clinical and experimental reports have been published on the subject. Strong evidence in support of the theory was that of Brooks, Johnson, and Kirtley, who reported that the incidence of massive gangrene in the extremities of rabbits was 14.5 times as high when the common and external iliac arteries alone were ligated as when the common iliac vein was ligated simultaneously. This result was not corroborated in experiments by Wilson.

Other important evidence comes indirectly from the reports of clinical improvement in circulation produced by the use of intermittent venous occlusion in peripheral vascular disease. Linton and his associates demonstrated experimentally with the thermostromuhr that concomitant venous occlusion increased the volume of the blood flowing in a ligated artery.

In carrying out our experiment two projects were undertaken. The first was to repeat the simple and logical experiment of Brooks and his associates. The second was to seek a more sensitive test for determination of circulatory changes in the limb following ligations of major vessels.

METHODS

Repetition of the experiment of Brooks, Johnson, and Kirtley. Rabbits were used. Under nembutal anesthesia the right common iliac and external iliac arteries were ligated

From the Harrison Department of Surgical Research Schools of Medicine University of Pennsylvania Philadelphia
This study is being carried further under a medical research contract with the United States Army

and divided through a transperitoneal incision. In another group of rabbits the right common iliac vein was ligated simultaneously with the arterial ligations. Repeated observations were made for 60 to 90 days, after which those animals which had survived were sacrificed and autopsies were performed whenever indicated.

With the exception of a single animal which died of an early massive gangrene about 36 hours postoperatively, we have excluded those animals which did not survive 48 hours postoperatively since rabbits are extremely sensitive to variable doses of anesthesia and to changes in climatic conditions. One hundred observations have been made—50 in each group.

The use of radioactive sodium in circulation studies—modification of the method of Smith and Quimby with dogs. With the dog lying on his back and each hind paw carefully strapped in place over the port in the lead shield covering the Geiger tube (Fig. 1), doses of 100 to 200 microcuries of radiosodium were injected into the jugular vein. Readings were taken continuously for 1 hour, alternating counts in each paw every minute. By this means relatively corresponding curves were obtained, representing the build-up of radiosodium ion concentration in the paws (Fig. 2). After normal controls had been established, the femoral vessels just below the inguinal ligaments were isolated under local anesthesia. Both superficial femoral arteries were ligated and divided, and the femoral vein on one side was ligated at the same level. Further doses of radioactive sodium were then injected into the jugular vein and similar readings taken immediately postoperatively and on the first and subsequent postoperative days. The total number of counts was charted, making necessary corrections for previous doses and

TABLE I—INCIDENCE OF COMPLICATIONS FOLLOWING LIGATION OF ILIAC VESSELS IN 100 RABBITS SURVIVING SURGERY 48 HOURS

	Artery only 50 rabbits per cent	Artery and vein 50 rabbits per cent
Massive gangrene	6	6

Contracture	36	22
Atrophy	60	36

changes in sensitivity of Geiger tubes Figure 3 represents curves obtained in this manner There were, however, wide individual variations

This method has not proved entirely satisfactory for our purposes because relatively large doses of radiosodium are required, each reading is continued for an hour, and the curves obtained proved to be at best qualitative whereas we were in search of an exact quantitative measurement of blood flow

The clearance method of Kety This is based on the assumption that radioactive sodium is a freely diffusible ion and if injected locally into muscle its rate of disappearance from the injection site is an index of effective circulation in that region A minute amount of sodium (50 to 100 microcuries in 0.1 c.c. of physiologic saline solution) was injected into the distal portion of the gastrocnemius muscle in the rabbits The portion of the leg injected was strapped over the port of the Geiger tube, and continuous readings were taken for a period of 15 minutes This series of counts produced an exponential curve which, when plotted on semilogarithmic paper, gave a straight line From the incidence of fall of this line a constant (K) was calculated which we have used as an index of the blood flow in the injected muscle

$$K = \frac{\log C_1 - \log C_2}{0.4343 (t_2 - t_1)}$$

C_1 = counts per minute at first reading

C_2 = counts per minute at second reading

t_1 = time at first reading

t_2 = time at second reading

0.4343 = log e

This technique was applied to a series of rabbits in which ligation of vessels was performed as described in the first method Curves obtained with this method were constant in shape and are illustrated in Figure 4

Fig 1 The γ ray counting tubes are kept in 2 inch thick lead shields and are connected as shown to the Geiger-Mueller counter The port in the shields is about the diameter of the Geiger tubes

RESULTS

1 The tabulations in Table I show considerable disagreement with the observations reported by Brooks and his associates Our incidence of early massive gangrene after common and external iliac artery ligation was only 6 per cent and was unaffected by simultaneous concomitant vein ligation The most characteristic effect resulting from either of these procedures was the development of late focal necrosis beginning in the skin of the paw and often resulting in complete necrosis and separation of the entire paw This effect occurred in 40 per cent of rabbits following arterial ligations alone and in 34 per cent of rabbits who had concomitant vein ligations The difference is not statistically significant There was a somewhat higher incidence of contractures (36 per cent compared to 22 per cent) when vein ligation was not performed

Fig 2 Type of curve obtained in both hind paws of a normal dog, representing the build up of radiosodium ion concentration after intravenous injection

SURGERY, GYNECOLOGY AND OBSTETRICS

Fig 3 Radioactive sodium build up curves in the hind paws of a dog preoperatively and immediately and on the first and seventh days after ligation of the left femoral artery and the right femoral artery and vein. The left

side showed a slower build up rate immediately after ligation but a faster one on the first and seventh postoperative days. These results were not consistent in all animals.

2 Using the radioactive sodium technique of Smith and Qumby we have obtained no statistically significant records because of a lack of accurate quantitative measurements and because we were unable to obtain constantly reproducible curves.

Fig 4. Curves obtained semilogarithmically after injecting radiosodium into the gastrocnemius muscles of a rabbit before and after ligation of the right iliac arteries and veins and measuring the rate of radiosodium clearance. The results which are shown in these curves are constantly reproducible.

3 The technique suggested to us by Kety yielded some most useful observations. By this method we have completed studies on 21 rabbits, some of which have been followed for over 2 months postoperatively. A number of others have been studied preoperatively and

Fig 5. The K values obtained in week recordings of radiosodium clearance in 21 rabbits, including 12 arterial and 9 arterial and venous ligations. A mean line is drawn to demonstrate the fact that the same general trend occurred in all animals, i.e., an immediate postoperative drop and then a gradual return to preoperative levels.

Fig 6 Demonstration in 4 rabbits showing that the rate of radiosodium clearance from the gastrocnemius muscle drops immediately after iliac arterial (or concom-

itant venous or both iliac arterial and concomitant venous) ligation and gradually returns to near preoperative levels

immediately postoperatively, but for various reasons (lack of a constant sodium supply, anesthetic deaths, etc) have not been followed sufficiently long to be included. However, the records that are not included because they lack completeness have conformed to the pattern of those shown (Fig 5, all K's, Fig 6, E5-A5, Y5-H5).

In Figure 5 are plotted the K values in these 21 animals week by week. Twelve arterial and 9 arterial and venous ligations are included here. Of this group 7 animals developed focal necrosis or contracture, 4 occurring in the combined ligation group and 3 in the arterial ligation group. The circulation in the gastrocnemius muscle of all of the animals determined in this way, regardless of which operative procedure was employed and regardless of the presence or absence of gross necrosis or contracture in the limb, followed the same general trend. There is an immediate postoperative drop in the circulation in the gastrocnemius muscle followed by a return to close to the preoperative flow during the next few weeks.

A simpler demonstration of this trend is given in Figure 6 representing 4 of the experiments. Two of each group are shown, and i-

stant venous or both iliac arterial and concomitant venous) ligation and gradually returns to near preoperative levels

of each group developed focal necrosis. In all 4 the immediate postoperative drop occurred, followed by recovery to near preoperative levels. Thus, we have observed that the circulation in the gastrocnemius muscle of the rabbit as determined by this method does not reveal what is occurring in the structures of the paw distal to it. Concomitant vein ligation has no effect on the clearance of radioactive sodium from the gastrocnemius.

DISCUSSION

The single striking feature in these experiments and in similar experiments of others is a serious lack of precise information about the peripheral circulation in the various component structures of the body. In an extremity which has been deprived of its major blood supply there have been few accurate measurements of blood flow in the skin, fascia, muscle, and bone. Thus, in these experiments, determination of blood flow in the gastrocnemius muscle gives inadequate indication of what is about to happen or has already happened to the paw just distal to it. Such fundamental phenomena require further investigation if we are to handle peripheral

SURGERY, GYNECOLOGY AND OBSTETRICS

vascular diseases and injuries on anything other than an empirical basis

The use of radioactive sodium, especially in the manner described by Kety, is proving to be most helpful in these problems. Perhaps intradermal sodium injections may help to give more information on the problem although technical difficulties made its use impractical in these experiments

CONCLUSION

We have been unable to determine that any benefit accrues from concomitant venous ligation in acute arterial occlusion. The evidence

of Brooks and his associates in support of this theory has not been confirmed. Studies of intramuscular circulation by use of radioactive sodium fail to show any improvement resulting from this procedure

THYROGLOSSAL TRACT ABNORMALITIES— CYSTS AND FISTULAS

Report of 105 Cases from the Johns Hopkins Hospital Observed during
the Years 1926 to 1946

GRANT E. WARD, M.D., JAMES W. HENDRICK, M.D., and
ROBERT G. CHAMBERS, M.D., Baltimore, Maryland

THYROGLOSSAL cysts and fistulas arise from epithelial rests in the remnants of the thyroglossal duct produced by the descent of the thyroid anlage. A brief review of the embryology shows that the thyroid anlage has its beginning as a diverticulum (i.e., evagination) from the floor of the pharynx, midway between the first and second pharyngeal grooves. Early in development, this anlage becomes a hollow stalked structure, known as the thyroglossal duct (23). This stalk usually loses its lumen to become a solid cord of epithelial tissue with its caudad, or pharyngeal end being marked by the foramen cecum at the base of the tongue. In the development of the embryo, the tongue forms at a later date than the thyroid anlage and the termination of the thyroglossal duct is buried within its substance. As a result of similar later development of the hyoid bone, the tract passes either anteriorly or posteriorly or through the hyoid. Caudal progression of the tract continues in the median line of the neck to a point below the thyroid cartilage where it terminates in the pyramidal lobe of the thyroid gland. Normally the epithelial lining of the tract undergoes degeneration and disappears (7, 12). When degeneration fails to take place, cysts or fistulas may occur anywhere along the course between the foramen cecum and the suprasternal notch. These cysts and fistulas are found either in the midline or slightly to one side. The drawings (Figs 1 and 2) illustrate where these lesions may occur, as determined by this series of cases.

Dr. Chambers is a cancer trainee at University of Maryland Medical School and a voluntary assistant in the Tumor Clinic, Johns Hopkins Hospital.

Histologically, the cyst or fistulous tract may be lined by stratified squamous, columnar, or transitional epithelium (Fig 3). After infection of the cyst or fistula, a heavy layer of fibrous connective tissue surrounds the tract. Lymphoid tissue, as seen in branchial cleft cysts and fistulas, is not observed in thyroglossal tract abnormalities (14). It has been reported that cancer may develop in the cyst wall or fistulous tract (7, 16). However, we have observed no neoplastic growths (23) in this present series.

Of the 105 cases seen in the Johns Hopkins Hospital, between 1926 and 1946, in 60 per cent the cysts or fistulas occurred between birth and the age of 10 years. The sex incidence was about equal for males and females there being 56 males and 49 females. These anomalies were noted in both white and colored patients. 70 cases were of the white race, and 35 of the colored race. In this series were seen all possible locations of the abnormality which have been reported: intratongue (4) (Fig 1, A and B), submental region (12), suprahyoid (11), at the level of the hyoid (12), infrahyoid (52), suprasternal (13), in the midline (19), to the right of the midline (13), and to the left of the midline (13). These locations are clinical, as noted in the hospital records and do not conform accurately to the anatomical locations of Figure 1. Too great an importance on these latter 2 figures cannot be stressed, since it is generally taught in the surgical text of today that thyroglossal tract abnormalities occur exactly in the midline (10, 12), and thus a great deal of confusion may be encountered.

Thyroglossal tract abnormalities are important, because they may be, and often are,

Fig 1

Fig 1 Illustrates various locations of remnants of the thyroglossal tract A, in front of foramen cecum, B, at foramen cecum, C, suprahyoid, D, infrahyoid, E, area of thyroid gland, and F, suprasternal

the seat of recurrent inflammatory disease and are a cause of cosmetic disfigurement. Infection occurring in these cysts is often the first direct symptom which causes the patient to seek medical aid. Recurrent infection was noted in 52 cases in this present series, which was extensive enough in 15 to cause spontaneous rupture of the cyst. Marked infection was present in 10 patients admitted to the hospital, and extensive cellulitis was present in 3, producing what is commonly termed "bull neck." In 6 of the 10 patients, the only treatment warranted after admission was incision and drainage. However, all of these 6 patients were subsequently readmitted for radical surgical procedure with complete elimination of the epithelial tract. The cyst can vary in size from several millimeters to 6 or 7 centimeters in diameter (Fig 4). A cyst located within the substance of the tongue usually presents the most alarming symptoms to the patient, such as, dysphasia, dysarthria, and choking sensations. Frequently, as cysts in the substance of the tongue or in the submental or suprahyoid area become larger, the patient notices tenseness in the tissues and also mild choking attacks.

The contents of the cyst is of a mucoid nature unless infection makes it purulent. Frequently, following infection, there is a rapid increase in the size of the cyst with pain and tenderness, and the cyst walls become thickened. Occasionally, there is a direct communication between the cyst and the foramen cecum, a thyroglossal tract sinus. In such a circumstance, pressure on the cyst will express fluid through the foramen cecum, thus clearly demonstrating a pharyngeal communication, present in only 2 of our cases. When infection occurs and progresses to suppuration with spontaneous rupture of the cyst, or if a cyst has been lanced, a sinus tract results. In this series, 34 per cent of the cases developed sinus tracts. Incision and drainage of a non-infected cyst, under any circumstances, is to be condemned.

In this series, admission examination revealed a cyst in evidence in 62 patients, or 59 per cent, a sinus tract in 36, or 34 per cent, and a palpable subcutaneous duct in 20, or 19 per cent. The term sinus tract is used to designate a discharging sinus in which the patient previously had a cyst which was lanced or became infected and suppurated (Fig 5). A

Fig 3 A sinus tract lined with squamous epithelium surrounded by dense fibrous tissue. There is an infiltration with lymphocytes, plasma cells, fibroblasts, and a few polymorphonuclear leucocytes. Striated muscle is also present.

definite cord of tissue palpated under the skin is termed "a congenital duct." Of the 20 cases reported, 6 were present without evidence of cysts. Of these 6 cases, 4 were incidental findings in the examination for another medical disorder, and the remaining 2 sought medical advice for an actual infection of the duct tract.

Of the 62 patients who presented a cyst when examined, 47, or 76 per cent, were midline lesions, and 15, or 24 per cent, were lateral to the midline. In this group of patients, 53, or 85 per cent, had cysts below the hyoid bone. There were 28 lesions above the hyoid bone, 9, or 33 per cent, were cysts, while 5, or 16 per cent, were sinuses, and the remaining 51 per cent presented combined lesions. When the 77 cases located below the hyoid were analyzed, 53, or 68 per cent, were cysts, 24, or 31 per cent, were sinuses, and the remaining 7, or 1 per cent, were combined lesions.

In making the diagnosis of thyroglossal tract cyst or fistula, it is to be remembered that the cyst or fistula may occur any place from the base of the tongue (foramen cecum) to the suprasternal notch, and that these abnormalities are the most frequent cysts or fistulas occurring in that area. Occasionally, as mentioned, they may occur just to the right or the left of the midline, but this deviation is not far enough to cause any difficulty

Fig 4 Typical example of a thyroglossal cyst located in the infrahyoid region.

in the differential diagnosis. One of our cases was located within the substance of the tongue above the foramen cecum (Fig 6). At examination, these cysts were smooth, ovoid or round, and translucent when examined with a transmitted light.

These cysts must be differentiated from a dermoid tumor, lipoma, sebaceous cyst, or from an enlargement of the pyramidal lobe of the thyroid gland, and enlarged lymphatic glands of the cricothyroid membrane. It was found that some of the cysts and fistulas were very superficially located, while others were quite deep. At operation, the lesions were found just beneath the skin, beneath the platysma muscle, beneath Colles' fascia, and still others beneath the pretracheal fascia. At examination, the tumor can usually be described as being cystic or fluctuant, but in 10 of these cases, the cyst was so tense that its cystic nature was overlooked and it was not until operation that the tentative diagnosis of a solid tumor was disproved. The cyst moved up and down with deglutition, and in the majority of cases movement of the cyst can be associated with movement of the hyoid bone. This was true in approximately 85 per cent of our cases.

Varying amounts of thyroid tissue may be found within the cystic mass or associated closely with it. This condition was present in 6 of our cases. It was noted in a 14 year old male who had a cyst measuring about 4 by 4

Fig 5 Thyroglossal sinus which resulted from the repeated incision of a cyst over a period of 20 years

centimeters in size that was within the substance of the tongue, anterior and above the foramen cecum. This patient had symptoms of a cyst for 11 years previous to admission to the hospital. The cyst was removed by local intraoral excision, and approximately 4 or 5 months following the operation, the patient developed symptoms of hypothyroidism, almost to the stage of cretinism. There was no palpable thyroid gland in the neck. This patient has been followed for a period of 21 years postoperatively, during which time it was necessary for him to continue taking thyroid extract regularly. At the present time he is completing a college education and is normal in every respect (Fig 6).

Thyroglossal tract fistulas or sinuses should not be confused with any other sinus tract. The opening of a branchial fistula or sinus tract is on the side of the neck and not "just to the right or left of the midline." Either fistulous tract may communicate with the oral cavity. If a thyroglossal tract fistula or sinus communicates with the oral cavity, it does so

always at the foramen cecum, whereas, branchial cleft fistulas or sinuses open at Rosenmueller's pouch in the lateral pharyngeal wall. If there is any doubt of the extent of the fistulous tract or sinus, it may be injected with a radio-opaque substance and a roentgenogram made. This injection is usually very painful and should be done only when necessary. However, if it is desired to visualize the fistulous tract with lipiodol for diagnosis, the external opening may be injected with a local anesthesia, a small catheter or lacrimal duct syringe passed just within the opening and 2 or 3 cubic centimeters of warm lipiodol solution injected.

TREATMENT

The treatment of thyroglossal tract abnormalities is entirely surgical excision of all the epithelial tissue. The authors would again like to stress the inadvisability of ever lancing a thyroglossal duct cyst unless it is infected and shows evidence of suppuration. Simple incision of the cyst serves no useful purpose, but does create a persistent draining sinus that is constantly discharging mucus and is very prone to become infected. In this series, in 21 cases the cysts had been lanced previous to the time the patients sought medical aid at the Johns Hopkins Hospital. All of these patients had very unsightly scars, and 18 had persistently draining sinuses. The election to incise and drain one of these cysts should rest on sound surgical judgment, such as would be used in determining when to open and drain any localized, fluctuant, obviously grossly infected lesion.

The injection of a sclerosing solution should never be used under any circumstances. The injected solution cannot be depended upon to reach all the minute epithelium-lined side pockets of the abnormality. Irradiation therapy, also, should not be used, since these lesions are not radiosensitive and the application of radium and x-ray serves only to complicate subsequent surgical procedures. One patient in this series was treated with radium which resulted in the destruction of so much skin that multiple plastic procedures were necessary to close the defect (Fig 7).

Gross and Connerley state that operative intervention for this disorder is not necessary

Fig 6 Patient with thyroglossal duct cyst located above the foramen cecum

in every case. However, we feel that by far the majority of these lesions will eventually become infected, and thus should be removed. In these cases, 54 (51%) gave a history of infection at some time during their course. Of these, 25 had gross infection when they sought aid at the Johns Hopkins Hospital. Certainly operative excision should be advised for all sinuses because of the high probability of recurring infection (Fig 5).

Regardless of the operative approach that is adopted for this condition, it is extremely necessary that the entire epithelial tract of the cyst, sinus, or fistula be completely removed. Forty-three of the patients in this group had a history of having had one or more surgical procedures previous to admission to the Johns Hopkins Hospital. Twenty-one patients gave a history of having had the cyst lanced, and 22 had local excisions of the abnormality.

Endotracheal anesthesia is the anesthesia of choice in removing these abnormalities.

The operative procedure outlined by Sistrunk (20, 21) in 1920 is the best basic procedure for radical removal of thyroglossal duct abnormalities (23). The authors believe that if the Sistrunk technique is carefully followed with a few modifications, there will be a minimal number of recurrences. It must be stressed that a midline vertical incision is contraindicated, as it does not give sufficient exposure and inevitably results in an unsightly midline contraction, which requires plastic procedures to correct. In following Sistrunk's principles, a transverse incision 5 to 8 centimeters in

Fig 7 Ugly scar after injudicious and repeated x ray treatment of a thyroglossal cyst.

length is made over the cyst, if a cyst is present, or an elliptical transverse incision around the opening of a sinus or fistula (Fig 8). The skin, subcutaneous tissue, and platysma muscle are reflected. The cyst or fistulous tract is followed to the level of the hyoid bone. At this point it will be noted that the longer fibers of the ribbon muscles, the sternohyoid, come into view. At the junction of these 2 muscles, the hyoid bone can readily be palpated. Again it should be stated that the fistulous tract can be anterior, posterior, or pass through the hyoid bone. In order to insure complete removal and to facilitate exposure above this point, the central portion of the hyoid bone is freed above and below, and 1 centimeter of the hyoid directly adjacent to the fistulous tract is removed with a generous block of tissue well around the sinus or fistulous tract. To facilitate the removal of a portion of the hyoid bone, the hyoid is grasped with forceps just to one side of the proposed site of resection. The bone is pulled forward and the center is removed with scis-

SURGERY, GYNECOLOGY AND OBSTETRICS

Fig 8 Illustrations of position of head and type of incision for removal of thyroglossal tract abnormalities in the upper neck. A similar type of incision is used for thyroglossal abnormalities in the lower part of the neck. (Redrawn from Sistrunk.)

Fig 9 Endotracheal tube in place. Assistant's finger in the mouth forces base of tongue and foramen cecum forward facilitating coming out stalk of tract. (Modified and redrawn from Sistrunk.)

sors if the patient is under 4 years of age, or cut with bone cutters in older patients. Tension on the fistulous tract will pull forward the centrally freed portion of the hyoid bone (Fig 9). Frequently the tract above the hyoid is very small and pliable and care must be exercised to prevent tearing it. An assistant's finger placed in the mouth, exerting pressure against the base of the tongue, forc-

ing it forward, greatly facilitates removal of a core of tissue, including the muscles around the stalk of the tract right up to the foramen cecum. The fainthearted will usually hesitate to follow this procedure, as he fears entering the mouth or the pharynx. However, in following this technique the tract may be followed to the base of the tongue and there removed with no untoward effects. Usually a

Fig 10 Method of suturing the hyoid bone and closing the wound Drain inserted (Redrawn from Sistrunk)

single pursestring suture of fine chromic catgut, carried on a round needle, will close the defect at the foramen cecum, inverting the mucosa into the mouth. The musculature of the tongue is brought together in the midline with interrupted sutures of fine silk or fine chromic catgut. The severed edges of the hyoid bone are brought together with catgut sutures placed directly through the bone, if the patient is in the younger age group, otherwise, the sutures are placed through the periosteum. It is not even necessary to approximate the edges of the hyoid. Such a defect will not result in any derangement of the action of the local muscles. A small rubber dam drain or tiny tube is placed deep in the muscles of the tongue to facilitate immediate postoperative drainage, and the skin edges are approximated with subcuticular and end-on mattress sutures of fine silk (Fig 10). Removing these skin sutures in a minimum of 4 days and a maximum of 5 days results in a fine hairline plastic scar, practically invisible after a few months, particularly if the patient is quite young.

When a sinus tract is present, the authors do not think it worthwhile to inject it with methylene blue or other dye to outline its course, as the dye frequently spills and stains the surrounding tissues. However, if the op-

erator desires to use a dye, it should be injected some 10 or 12 hours preoperatively to allow the dye to become fixed to the tissues of the sinus tract. Then, at operation, even if there is spillage into surrounding tissues, the sinus tract itself will be more deeply stained. However, any fistulous tract can be followed sufficiently without the aid of one of the dyes.

The 4 intratongue lesions in the series were all excised intraorally. None of these recurred.

RESULTS

Of the 105 cases studied, all were followed for a year or more. Seventy-eight, or 75 per cent, were followed for 5 years or more. The following statistics were based on the total 105 cases.

In the 28 suprahyoid lesions, it was not felt necessary to remove an area of the hyoid bone, but the lesion was followed to the foramen cecum in each case and a core of tissue was removed well around it. None of these lesions recurred, a cure rate of 100 per cent.

Of the 77 which occurred at or below the hyoid bone, 34 had an adequate section of the bone removed, 2, or 6 per cent, recurred.

In 43 of the 77 at or below the hyoid, no bone was removed and 11, or 25.6 per cent, recurred. These figures are evidence enough

to prove the value of removal of the central portion of the hyoid bone in order to follow the tract to the foramen cecum

There were 13 recurrences in the entire series. In all but 2 of these cases, no hyoid bone was taken in the first operation. In these 2 cases, the authors feel insufficient bone was taken. In one of the cases, several small bits of hyoid were rongeured away, and in the other, the hyoid was touched with carbolic acid, both procedures to be condemned. In the reoperative cases, an adequate amount of hyoid bone was taken at the second operation. These reoperative cases have been followed from 1 to 15 years. In none were there recurrences following the second operation. In this series there were no operative deaths. One patient, mentioned before developed hypothyroidism 4 months after operation following the removal of an intralingual cyst, the wall of which contained the only thyroid tissue in the body. As mentioned before, 6 patients presented themselves with serious acute infection and were preliminarily treated by simple incision and drainage. Eight of the cases, after pathological study, revealed aberrant thyroid tissue within the wall of the cyst. In 6 of these cases, this aberrant tissue was embryological in structure.

CONCLUSION

Failures in this series, as well as in other reported series, are due to the inexperienced operator seldom appreciating the fact that it is necessary that thyroglossal tract abnormalities be followed to the foramen cecum at the base of the tongue, and that it is necessary in all instances to insure complete removal of all epithelial remnants, and in all lesions at the level of the hyoid bone or below to take 1 centimeter of the central portion of the hyoid bone and a block of tissue well around the

sinus or fistulous tract. There are undoubtedly some few cases in which an incomplete procedure will result in a permanent cure, but this can be due to the chance that no epithelium lies within or near the hyoid bone. Simple dissection of the cyst, combined with simple ligation of the thyroglossal pedicle, and the treatment of thyroglossal fistula by means of scraping and cauterizing, the injection of sclerosing solutions, lancing the cyst, and treating the abnormality with x-ray or radium, give unsatisfactory results, serve only to increase the incidence of recurrence, and should be discarded (23).

ERADICATION OF BENIGN LYTIC BONE TUMORS AND IMMEDIATE RECONSTRUCTIVE SURGERY WITH EMPHASIS ON BENIGN GIANT CELL TUMORS

DANIEL H. LEVINTHAL, M.D., F.A.C.S., Beverly Hills, California, and
GEORGE L. KRAFT, M.D., North Hollywood, California

A STUDY of benign lytic lesions of bone still attracts considerable attention because of the confusion in the diagnosis and methods of treatment.

The etiology of benign giant cell tumor, localized osteitis fibrosa cystica, osteoid osteoma, and eosinophilic granuloma is not known but it appears to be directly concerned with an interference of blood supply, and trauma is a very likely contributing factor. Some writers consider these lesions as essentially inflammatory, others speak for the neoplastic theory. Codman thought that benign giant cell tumor represented a process of repair following rupture of a nutrient artery. The theory of the embryological basis for enchondromas is well known.

Bergstrand in writing on the genesis of giant cell tumor states that this condition is neither a tumor nor an inflammation but rather a process intimately associated with normal bone formation and resorption (Haggquist-Hansen theory). He states that while he does not know the genesis he regards the condition as due to local bone resorption and based his opinion on the similarity of giant cell tumor to osteitis fibrosa cystica. While the cause is not known, certain observations favor assumption of the primary cause as due to disturbed circulation.

Decalcification and resorption of collagenous materials in the bone sets free the original bone forming tissue. Bone corpuscles approach each other and by fusion and nuclear division form giant cells. These form a syncytium lining the lumina of vessels, thus differentiating a fibrous bone marrow which replaces resorbed bone substance, proliferates and displaces true bone marrow, a reversion

of bone tissue to primitive fetal type. This tendency to proliferation gradually ceases, giant cells disappear, and regression occurs. The ultimate result is a bone cyst surrounded by new bone tissue.

Eosinophilic granuloma of bone is a destructive lesion in which histiocytes form the basic component of the lesion interspersed with varying numbers of eosinophilic leucocytes. Lichtenstein and Jaffe (26) were the first to describe this condition and give it its name. Green and Farber (16) were the first to show the relationship of this condition to that of Letterer-Siwe disease and that of Hand-Schüller-Christian disease. Farber and Mallory believe that all these conditions are different expressions of the same basic disorder.

Osteoid osteoma was first described as a clinical entity by Jaffe (23) who believes that it is of neoplastic origin while other authors such as Brailsford believe it is inflammatory in origin. Ponseti and C. K. Barta describing the pathological picture bring out the fact that the typical histological appearance, the lack of inflammatory cells, and the negative smear and culture would indicate its neoplastic origin, however clinically and roentgenographically it appears to be a lesion of inflammatory origin.

Inclan believes that characteristics of giant cell tumor are more truly those of benign tumor rather than those of chronic inflammation, chronic irritation, or traumatic subcortical hemorrhage in cancellous bone.

Ernest E. Aegerter states that the giant cells found in such tumors as giant cell tumor of bone, giant cell tumor of tendons, osteogenic sarcoma, fibrous dysplasia (hyperparathyroidism), unicameral cyst, osteoid osteoma, eosinophilic granuloma and allied reticu-

From the Orthopedic Departments, St. John's Hospital, Santa Monica, and St. Joseph's Hospital, Burbank, California.

Fig 1 Curettage and suction in removal of giant cell tumor

loendothelioses, nonosteogenic fibroma and ossifying fibroma are all generically and functionally related, produced by the fusion of fibroblastic tumor cells for the purpose of phagocytosis. He states further that "the behavior of the tumor can be predicted only by the consideration of the cells of the fibrous matrix and that the giant cells give little or no clue as to whether the tumor will recur or metastasize. Fibrous matrix cells are found also in a number of bone lesions, both neoplastic and non-neoplastic. Many diagnoses of giant cell tumor of bone are based on these two criteria alone which is a mistake. The terminology would be self-explanatory and

classification simplified if fibromas of bone were called giant cell fibroma, nonosteogenic fibroma and ossifying fibroma."

The lytic lesions of fibrous dysplasia of bone, osteitis fibrosa cystica generalisata, or von Recklinghausen's disease, present a picture which may very easily be confused with metastatic carcinoma. The etiology of these lesions is definitely known as an adenoma of a parathyroid gland. The diagnosis is made from a careful history, absence of a primary lesion, hypercalcinuria, hypercalcemia, hypophosphatemia, and renal calcinosis.

The purpose of this presentation is not to review the details of the various etiological theories, nor to delve at length into the pathological findings of these lesions, which are so well described in numerous writings, but rather to discuss the methods of treatment and to suggest some refinements in technique.

The diagnosis of giant cell tumor is made by the complaints of localized pain, swelling, impaired function, and a crackling or give sensation. The usual location is at the end of certain long bones, especially the distal end of the femur, the proximal end of the tibia, proximal end of the fibula, the distal end of the radius, and the proximal end of the humerus. Other bones including the vertebrae are frequently involved. The roentgenogram is often diagnostic, showing widening, rarefaction, and

Fig 3 Case 1 A K, 10 $\frac{1}{4}$ years of age Localized osteitis fibrosa cystica a, Before surgery, b, 5 months after surgery, curettage, aspiration, tubal grafts (struts and chips)

occasional trabeculation of the medulla, with thinning and bulging of the cortex

Grout discusses the difficulties of roentgenological interpretation and misunderstandings which are liable to occur if too much stress is placed on roentgenographic features without reference to clinical findings and other means of investigation He believes that it is not scientific to state that roentgenographic features alone are sufficient to establish the nature of any bone tumor He shows series of roentgenograms of sunray appearance considered to be typical of osteogenic sarcoma which in each case showed a different pathological condition The same situation was present with various osteolytic lesions

Brailsford states that it is very important to correlate the clinical, roentgenological, and histological findings before radical surgery such as amputation is performed He cites a number of cases showing roentgenograms typical of osteogenic sarcoma which proved to be benign He also presents a case in which, although the clinical findings did not substantiate the diagnosis of a Ewing's sarcoma, the roentgenogram suggested and the biopsy revealed a highly malignant Ewing's tumor The patient refused surgery The lesion completely resolved and 10 years after she is still fit and well

The treatment of benign giant cell tumors, localized osteitis fibrosa cystica, enchondroma, osteoid osteoma and eosinophilic granuloma and some others of the benign lytic bone lesions, seems to vary, depending to some extent upon the specialty of the attending physician,

Fig 4 Case 2 N O'B, 4 years of age Localized osteitis fibrosa cystica a, Before surgery, b, microscopic section showing the marrow space diffusely replaced by young connective tissue cells with a number of blood vessels, there is no evidence of malignancy, c, anteroposterior and lateral views showing gradual reossification of the involved area, 13 months after surgery

the radiologists favoring irradiation and the surgeons, resection, while a few clinicians favor both Of the latter group, some speak for preoperative irradiation and others suggest postoperative therapy, and one surgeon gives his patients with giant cell tumors irradiation before and after surgery

Badgley, discussing the presentation of Meyerding, states that a combination of roentgen therapy and surgery gives poorer results than either alone He believes that radiation following operation and the employment of bone grafts may prevent creeping substitution in the grafts

Hatcher, discussing Meyerding's presentation, says that it is possible that some benign giant cell tumors which have been reported to undergo malignant changes are examples of sarcoma induced by roentgen therapeutic ir-

Fig 5 Case 3 H B, 7 years of age Localized osteitis fibrosa cystica a, Before surgery, November 11, 1931, b, after 2,400 milligram hours radium, June 3, 1932, c, approximately 2 months after surgery, January 1933

ntation, but emphasizes that this is true in cases treated in which the indications and dosage were not so well known and controlled as they are now

Mandl does not favor preoperative irradiation

Cantril and Buschke state that roentgen therapy of giant cell tumors is a highly satisfactory procedure They state that curettage is unsatisfactory because of the frequent recurrences (30 per cent) It increases the danger of infection and may make roentgen therapy more risky and difficult They prescribe x-ray therapy in minimal dosage sufficient to destroy the tumor but not to interfere with regeneration of bone

Haggart and Hare believe it erroneous to warn against combined radiation therapy and surgery in the management of giant cell tumor

Woodard and Coley (42) after treatment of 11 giant cell tumors with irradiation have come to the conclusion that they should not be treated by irradiation

Cahan and his associates feel that irradiation

therapy is far less satisfactory than surgical treatment Irradiation therapy carries the risk of inadequate treatment of a malignant tumor in the mistaken belief that it is benign, that many of these benign lesions are radioresistant or only slightly radioresponsive, that the growth centers of children may be seriously disturbed, and that sarcoma may develop at the site of previous irradiation

They describe 11 cases in which bone sarcoma developed at a period long after irradiation of benign tumors In our rather small series of proved benign giant cell tumors, 2 patients (H D and P O'L) developed post-irradiation sarcoma The question arises whether these 2 patients may not have developed sarcoma if they had not had irradiation The biopsy sections following the original surgery in these cases had been carefully checked by several pathologists The entire tumor had been resected It is presumed therefore that there had been no error in the original diagnosis, and that the resulting sarcomas had been caused by the irradiation

Fig 6 Case 4 P O'L, 15 years of age Xanthomatous bone cyst left femur a, March 5, 1936, on admission, b, July 7, 1936, after curettage and massive grafts and bone

chips, c, April 1, 1937, healing, film made during x-ray therapy, d, April 4, 1940, 4 years postoperative, showing malignant degeneration of ilium and upper end of femur

With these divergent expert opinions, how should the local clinician or radiologist decide upon the course to pursue in a given case? The majority of these patients are originally seen by men in general practice and the diagnosis is made with the assistance of the local roentgenologist. Too few of these patients are seen early by the expert roentgenologist, general surgeon, or orthopedic surgeon. A more definite conclusion regarding the method of treatment offering the best end result with a minimum of functional loss and minimal disability may only be determined by more extensive and better illustrated literature on this subject. Good roentgenographic reproductions showing the extent of involvement at various stages of the treatment and the end results, good, bad, or indifferent should be published.

Geschickter (14), in evaluating the treatment of giant cell tumor by surgery or irradiation, chooses a middle ground. He states that surgery can be used following irradiation if the latter is properly given, while irradiation following unsuccessful surgery is usually useless. H. Platt favors surgery in the treatment of benign giant cell tumors. Geschickter and Copeland (15) state that "excluding isolated giant cell tumors of the skull and vertebrae, curettage performed in carefully selected cases is unquestionably the treatment of choice." Bloodgood favored thorough curettage fol-

lowed by cauterization with pure phenol, later neutralized by 95 per cent alcohol. Some surgeons use a 50 per cent zinc chloride solution. The electric cautery or soldering iron was often substituted for the chemical cauterization.

Herendeen (20, 21) favors primary roentgen therapy without operation. He gives "growth

Fig 7 Same patient as in Figure 6. Photomicrograph (X145) original biopsy. Tissue from the wall of the cyst reveals a very cellular fibrillar connective tissue infiltrated with small round cells. In places there are nests of large foamy cells with a small eccentric nucleus and vacuolated cytoplasm. Sudan 3 stain reveals the cytoplasm contains lipid material. The contents of the cyst shows a similar structure with single foreign body giant cells. Single foci of new bone formation imbedded in the cellular tissue. The histological picture suggestive of xanthomatous bone cyst.

Fig 8 Case 5 J S, 28 years of age Benign giant cell tumor a, b, and c, Anteroposterior, lateral, and oblique views showing lytic lesion of medial condyle, d and e, roentgenograms 5 months postoperative showing reconstruction

cell tumor and in the repair of malacic fracture in osteitis fibrosa cystica localisata," we have observed excellent spontaneous repair in the latter following fracture without irradiation or any other treatment except immobilization

Pierce (33, 34, 36) reported 2 cases of malignant degeneration of giant cell tumor or of concurrent origin of malignant neoplasm

W B Coley was opposed to irradiation following curettage, stating that either surgery or irradiation but not both should be used It was his opinion that a higher percentage of malignant growths followed irradiation of benign lesions after surgery Coley believed that 16 per cent of benign giant cell tumors became malignant He favored surgery, cauterization, and complete closure of the wound

Simmons, in a review of the cases in the registry of the American College of Surgeons, reports 3 cases or 3.7 per cent of benign giant cell tumors changed to osteogenic sarcoma, but there is no conclusive evidence that the original diagnoses may not have been erroneous It is frequently possible for a poorly located specimen to be given to the pathologist for the original diagnostic examination The biopsy specimen may be taken from a portion of the mass which is not typical of the tumor proper *The pathologist can only report on the specimen presented to him by the surgeon*

restraint" dosages, which are followed by apparent tumor growth and later regression Pain and tenderness diminish as the reaction subsides ossification takes place, and function returns Results are not evident for months

Pierce (35) agrees with Herendeen and Pfahler He favors frequent relatively mild doses of roentgen therapy with the purpose of growth restraint It is his opinion that surgical intervention should not follow roentgen therapy short of 6 or 8 weeks In his series of cases there was a less favorable response following surgical intervention Pierce favors immediate roentgen therapy, if surgical intervention has already been accomplished, especially if there has been no cauterization at the time of operation

While Pierce speaks of the "specificity of irradiation in inducing ossification of giant

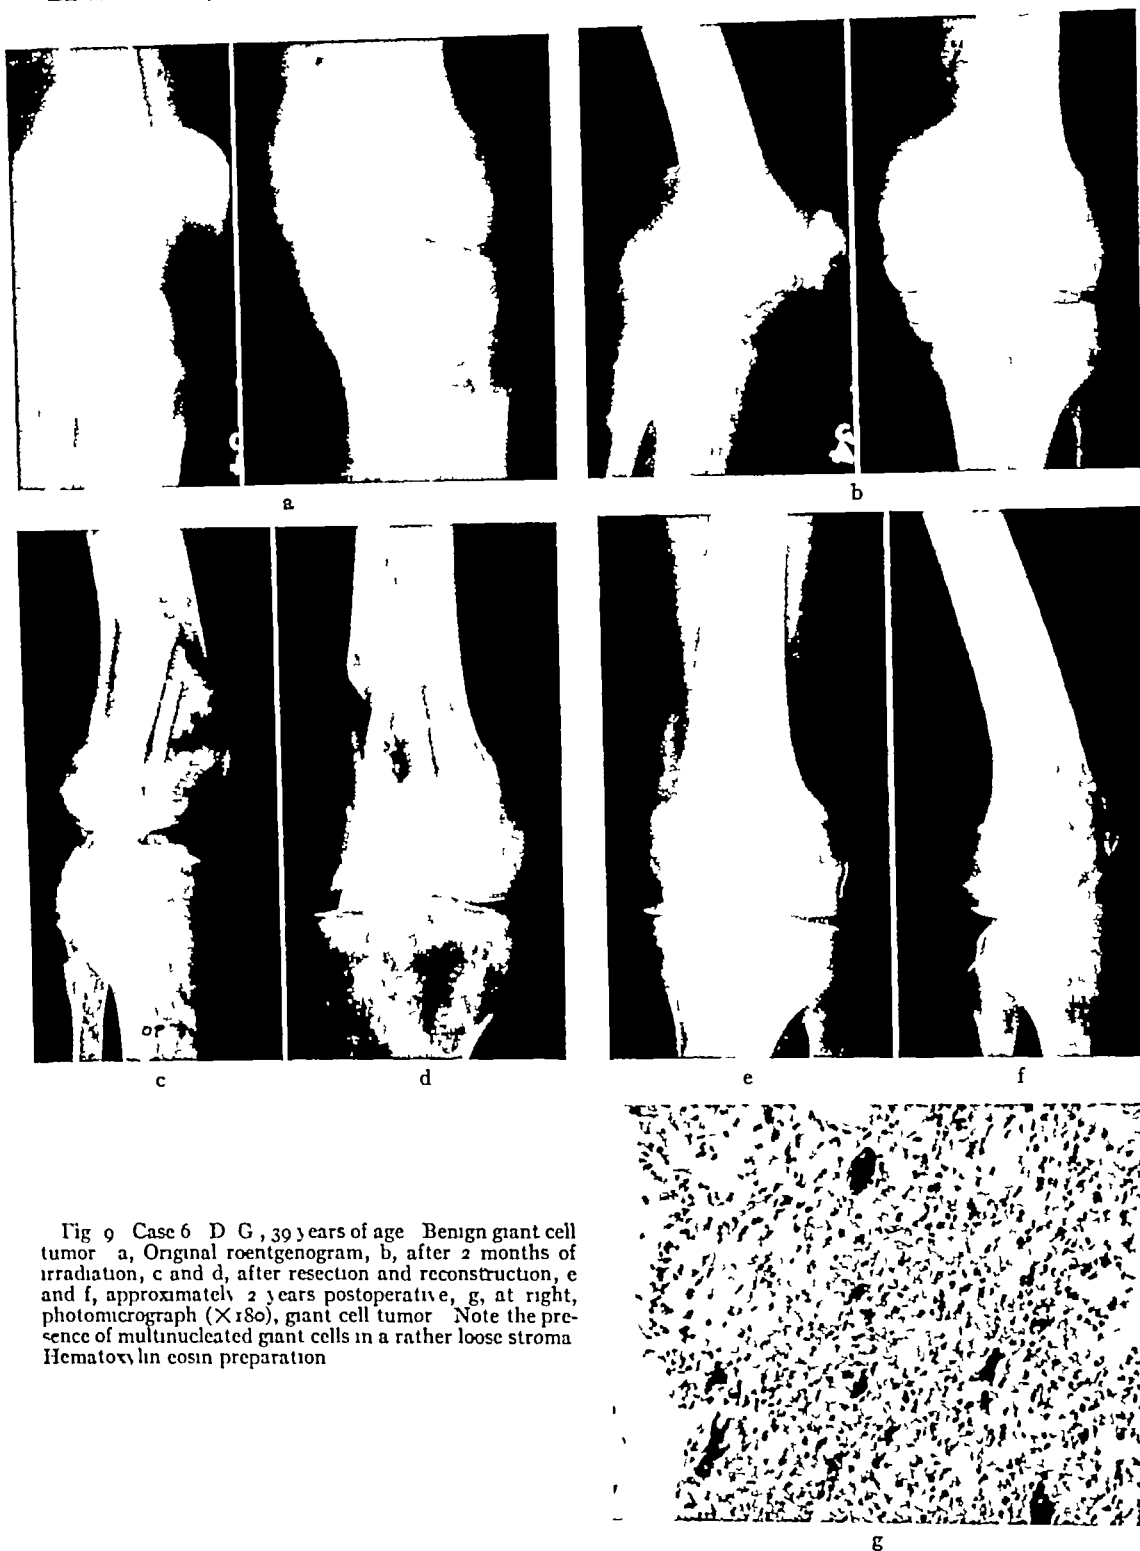

Fig 9 Case 6 D G, 39 years of age Benign giant cell tumor a, Original roentgenogram, b, after 2 months of irradiation, c and d, after resection and reconstruction, e and f, approximately 2 years postoperative, g, at right, photomicrograph ($\times 180$), giant cell tumor Note the presence of multinucleated giant cells in a rather loose stroma Hematoxylin eosin preparation

Fig 10 Case 7 E G, 15 years of age Localized osteitis fibrosa cystica neck of the left femur a, Before surgery, b, reconstruction with iliac grafts Roentgenograms 2 months postoperative

Biopsy specimens should, therefore, be taken from the depth and also from various areas of the tumor mass and preferably en bloc

Stone and Ewing reported a case of malignancy of bone occurring at least coincidentally with a giant cell tumor

Mercer reports recurrence following curettage He evidently feels that some of the giant cell tumors undergo malignant degeneration, and that some are infected and in other cases there is failure of healing of the large cavity He states that "deep x-ray therapy gives reasonable hope of permanent cure although in 3 or 4 weeks after treatment, the appearance is that of a rapidly growing malignant tumor This acute phase quickly subsides and fibrosis with rapid regression of the tumor results"

Jones and Lovett describe the giant cell tumor as a collection of spindle cells with numerous multinuclear giant cells The growth has no tendency to metastasize and can be removed locally

While most authors have discarded the term "sarcoma" for that of benign giant cell tumor, it is regrettable that Whitman states that "in comparison with most sarcomata, giant cell sarcoma is a tumor which is clinically benign" Baetjer and Waters have a page "giant cell sarcoma" and then state that it has a "malignant name but is entirely benign in character," and Albee under the

title, "The Treatment of Primary Malignant Changes of Bone by Radical Resection and Bone Graft Replacement," includes in his report 2 and perhaps 3 cases of benign giant cell tumor Such repetition of errors of nomenclature confuses the students and clinicians and should be eliminated from the literature

The writers present some cases of benign lytic bone lesions, treated by curettage, aspiration, primary excision or resection, followed by immediate reconstructive surgery The technique described has the following advantages (1) more definite and time saving end results, (2) immediate cessation of the destructive process, diminishing the extent of necessary reconstruction in direct proportion to the time elapsing since onset

At operation, under tourniquet, an incision is made directly into the tumor which in benign giant cell tumor consists of a current jelly, fleshy mass containing some serosanguineous fluid Frozen section confirms the diagnosis in the operating room and the writers proceed with the technique of resection Depending upon the size, location, and nature of the lesion it may be eradicated by a thorough intrinsic curettage or by an extrinsic total resection

In the intrinsic method a long window is cut over the tumor so that all sides and ends are in full view The mass is resected grossly and then a curette is employed, at the same time constantly using a large caliber rubber suction tube attached to a strong suction apparatus (Fig 1) Substitute hose is at hand to be changed as frequently as is necessary during the operation Each locus is cleansed of tumor tissue with the curet and the suction apparatus When the entire inside of the cavity can be seen thoroughly cleansed of tumor tissue, a ball electrode endotherm is used to cauterize the entire wall It is then filled with saline solution, the large suction tube is again inserted and the walls are again curetted, and the contents thoroughly aspirated For the bone grafts, cancellous bone is obtained from the wing of the ileum Mowlen and Abbott and associates have shown that cancellous bone is able to withstand infection to an unusual degree, because of its loose structure it acquires an adequate blood

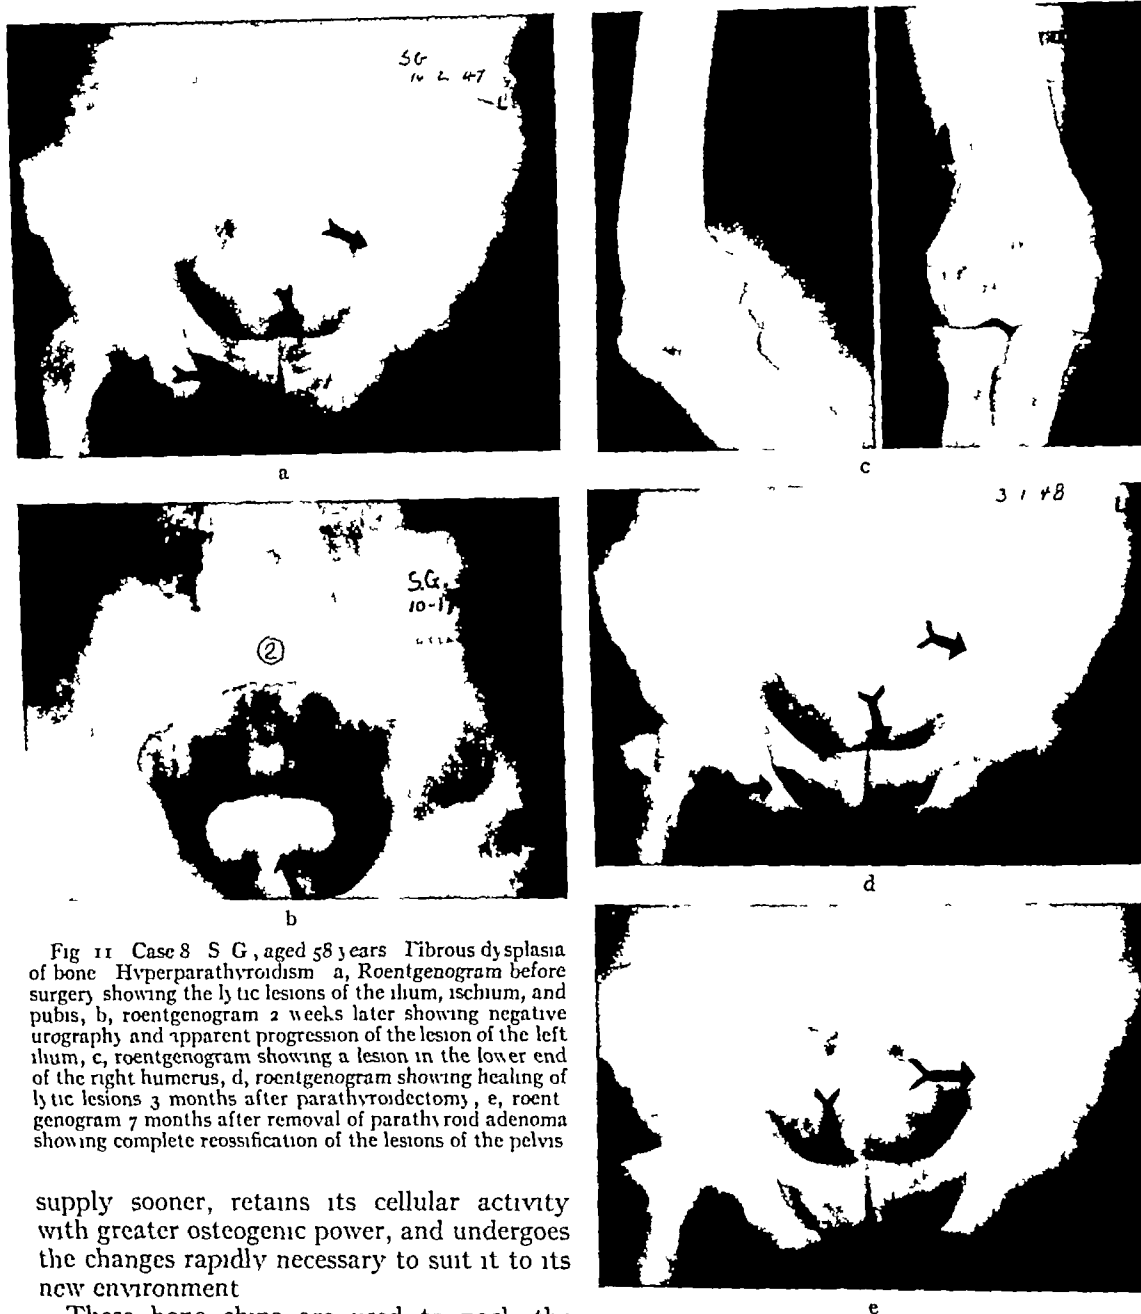

Fig 11 Case 8 S G, aged 58 years Fibrous dysplasia of bone Hyperparathyroidism a, Roentgenogram before surgery showing the lytic lesions of the ilium, ischium, and pubis, b, roentgenogram 2 weeks later showing negative urography and apparent progression of the lesion of the left ilium, c, roentgenogram showing a lesion in the lower end of the right humerus, d, roentgenogram showing healing of lytic lesions 3 months after parathyroidectomy, e, roentgenogram 7 months after removal of parathyroid adenoma showing complete reossification of the lesions of the pelvis

supply sooner, retains its cellular activity with greater osteogenic power, and undergoes the changes rapidly necessary to suit it to its new environment

These bone chips are used to pack the cavity Where structural support is necessary long cortical bone grafts are obtained from the tibia and used in strut-like fashion in the longitudinal axis of the cavity The soft tissues are sutured tightly by layers, with chromic catgut used throughout including the skin

so that dressings are unnecessary A well fitting plaster cast is applied This remains on for approximately 3 months, during which time check-up roentgenograms are made at intervals of 4 to 6 weeks When indicated, a brace is used after the removal of the cast

Fig 12 (Legend opposite page)

The extrinsic or total extraperiosteal resection is done in cases in which there is extreme thinning out or destruction of the cortex. Reconstruction is done by the use of thick autogenous bone grafts for structural support with numerous cancellous bone chips for its osteogenic power. Wherever applicable anatomical reconstruction should be attempted (Levinthal and Kirshbaum).

For several years, the writers have used a technique of small pedicled tooth-like grafts across the tibial channel of the donor site to hasten regeneration of bone following removal of massive grafts (Fig 2). This method also prevents depression of the scar.

CASE REPORTS

CASE 1 A K, aged 10½ years, Michael Reese Hospital. In 1933, the patient fell from a tree and fractured his left shoulder. In January 1936, the same shoulder was injured when struck by a truck. In April, 1936, the same shoulder was again injured by falling. Examination at this time revealed a fusiform tender expansion of the proximal end of the right humerus. Roentgenogram showed a multilocular cystic area expanding the upper one third of metaphysis (Fig 3, a). There was no evidence of a pathologic condition in any of the other long bones.

Operation was performed on May 19, 1936. Curettage and aspiration were done followed by the use of tibial grafts to fill the defect. The pathologist's diagnosis concurred with the clinical diagnosis of osteitis fibrosa cystica. Patient made uneventful recovery with a complete return of function (Fig 3, b).

Fig 12 Case 9 B S, 16 years of age Fibroma of the middle metacarpal bone a, Roentgenogram before operation, showing expanding lytic tumor of the middle metacarpal bone Complete destruction of the shaft including

CASE 2 N O'B, aged 4 years, Michael Reese Hospital There was a history of right limp and pain in the right hip region of 3 months' duration The physical examination revealed tenderness about the right great trochanteric region, swelling, and limp There was no local heat or redness Roentgenograms revealed a multilocular cystic lesion of the proximal metaphysis of the right femur extending to the epiphyseal plate (Fig 4, a)

At operation on August 15, 1936, a window was opened into this cavity This was curetted, aspirated, cauterized with 50 per cent zinc chloride solution, washed and again aspirated The cavity was then filled with cancellous bone chips taken from the ilium The pathologist's report was osteitis fibrosa cystica with giant cells (Fig 4, b)

Recovery was uneventful, and the follow-up roentgenograms show gradual reossification of the involved area and reconstruction of the normal architecture of the upper end of the femur (Fig 4, c) The patient has had no residual symptoms

CASE 3 H B, aged 7 years, Michael Reese Hospital There was a history of pain and swelling of the right forearm following an injury of about a week's duration Roentgenograms showed an expanding cyst of the left ulna The patient had 2,400 milligram hours of radium on November 17 and 18, 1931 November 8, 1932, because of expansion of the cyst, operation was advised Through a small incision, the cyst wall was opened, curetted, and aspirated, and the lateral wall gently compressed with the flat surface of a small periosteal elevator On January, 1933 check-up of roentgenograms show regeneration of bone within the former cystic area

cortex, some trabeculation There is a thin remnant of bone of fairly normal density in the subchondral region of the head of the metacarpal, and about 1 centimeter of normal appearing bone at the proximal end Note the shortening of the metacarpal, b, roentgenogram showing reconstruction of metacarpal by tibial graft Note restored length of the finger, c, photomicrograph of the tumor mass Note the dense fibrillar appearance of the lesion and in one area a spicule of bone, d, roentgenographic appearance 27 months after operation showing transformation of graft into a true metacarpal bone, e, photographs showing extension and flexion, f, photographs 27 months after operation showing restored length of right middle finger, full extension, and very moderate limitation of flexion

Eventually there was recovery of form and function and the patient was symptom free

CASE 4 P O'L, aged 15 years, Cook County Hospital Patient gave history of developing pain and limp in left hip about December 1934 In March of 1935 while walking her leg suddenly gave way She was admitted to the hospital on March 12, 1936 Roentgenogram taken at this time (Fig 6, a) showed a multilocular area in the upper end of the left femur and a pathological fracture of the neck of the femur

Surgery was performed on March 23, 1936 at which time the large yellow tumor mass was curetted, aspirated, and cauterized Bone grafts obtained from the tibia and the ilium were used to fill the bone defect The microscopic diagnosis of this tumor was xanthomatous bone cyst (Fig 7)

The patient's postoperative course was smooth She received x-ray therapy as a part of her follow up treatment Roentgenograms April 1, 1937 show regeneration of bone in the pre-existing cavity with union of the fractured neck of the femur (Fig 6, c)

Four years later patient complained of pain, loss of weight, and swelling localized to left hip region Roentgenograms showed sclerosing osteogenic sarcoma verified by biopsy The patient died of pulmonary metastases about 1 year later

CASE 5 J S, aged 28 years, Michael Reese Hospital Patient gave a history of pain first developing in the region of the left knee in November, 1935 Consulted us on February 15, 1936 Examination revealed moderate tenderness over the medial condyle of the left femur and an eggshell feeling or crackling on deep pressure over that area Roentgenograms (Fig 8 a, b, c) show a lytic lesion with slight trabecu-

Fig 13 Case 10 Y B, aged 22 years Benign giant cell tumor of the femur a and b, Before operation, c and d after resection and reconstruction

lation involving the medial condyle of the left femur. The Wassermann and Kahn tests were negative.

On February 29, 1936, surgery was performed. The tumor was excised grossly and frozen sections showed benign giant cell tumor, highly cellular. Thorough curettage, irrigation suction, and cauterization with a ball electrode endotherm were used. The defect was filled with numerous cancellous grafts as well as cortical strut grafts obtained from the tibia. Cast was applied. The cast was removed 3 months later. Roentgenograms taken July 27, 1936 show reconstruction (Fig 8 d, e).

CASE 6 D G, aged 39 years, Michael Reese Hospital. The patient gave a history of pain in the left knee since 1931. From then until 1934 he had been treated for "rheumatism." In April 1934 he slipped while getting out of the bath tub and forcibly bent his left knee causing a loud crackling and tearing of the joint. He had a great deal of pain and disability until he was seen at a clinic on May 1934, at which place he was told he had a tumor requiring irradiation. He was also informed that he had a 3 plus Wassermann and diabetes. He was given deep x ray therapy until July 11, 1934, at which time further roentgenograms were made. The patient was then told he had a malignant tumor requiring amputation. He was admitted to the Michael Reese Hospital on July 20, 1934. The Wassermann and Kahn tests were negative and there was no glycosuria nor hyperglycemia.

On July 21, 1934, the patient was operated upon. The mass was completely excised including the medial articular surface of the condyle since the tumor involved the entire subchondral plate. The soft structures and remaining bone surfaces were care-

fully curetted and irrigated, the large tube suction apparatus being used frequently. A ball electrode endotherm was used for cauterizing. Two cavities were then made into the head of the medial articular surface of the tibia and numerous strut grafts were taken from the tibial shaft and placed across from the shaft of the femur into the tibial head (Fig 9). A spica cast was applied for 3 months followed by the use of a walking caliper brace. Brace was discarded in November 1935, at which time patient had an excellent fusion.

CASE 7 E G, aged 15 years, Michael Reese Hospital. The patient was observed in October 1941, complaining of pain, limited motion, and limp. The symptoms were all referred to the region of the left hip. Operation consisted of an anterior approach to the neck of the left femur. Curettage, aspiration, and cauterization were followed by the insertion of grafts obtained from the wing of the ilium. Roentgenograms made January 10, 1942 (Fig 10 b) show the reconstruction. Six months postoperatively the patient was symptom free.

CASE 8 S G, aged 58 years, St John's Hospital, Santa Monica. The history is that of pain in the left groin and anterior aspect of the left thigh of 8 months' duration. On October 2, 1947, the patient presented himself in the outpatient department of St John's Hospital walking with the aid of crutches. His condition had been studied at another clinic and diagnosed as metastatic carcinoma of the bones, because of numerous lytic lesions involving the wing of the left ilium extending into the acetabular cavity, the right elbow, ischium and pubes, and the region of the left lesser trochanter. Additional lesions were noted in the left femur, both ilia, and the skull.

A complete study revealed no primary lesion. The patient had lost no weight. The routine blood count was normal. Blood chemistries showed calcium of 13.5 milligrams per cent, phosphorous 9.9 milligrams per cent, and alkaline phosphatase of 1.7 King-Armstrong units. There was hypercalciuria. The sedimentation rate was 40 millimeters in 1 hour. Recheck blood calcium was 15 milligrams per cent. On November 15, 1947, a biopsy was taken from the large lesion in the supra-acetabular region of the left hip (Fig 11 a). The pathologist, Dr Hummer, reported fibrous dysplasia, confirming the clinical diagnosis.

On December 9, 1947, the neck was explored. A benign calcified adenoma of one of the left parathyroids was removed from within the capsule of the thyroid gland. The blood chemistries immediately returned to normal values. Subsequent roentgenograms showed gradual recalcification of the lytic bone lesions (Fig 11, d, e).

On observation in the clinic in September 1948, the patient walked without crutches and with a slight limp. He had no pain and had returned to his previous occupation. The blood chemistries remained normal.

CASE 9. B. S., aged 16 years, Cook County Hospital. This patient was first seen in the out patient clinic on February 11, 1936. The complaint was a progressive swelling of the dorsum and palm of the right hand. This was first noticed about a year prior to her admission to the Cook County Hospital. The roentgenograms showed a lytic expanding tumor of the middle metacarpal bone with absence of the cortex along parts of the shaft. The base was uninvolved for about 1 centimeter (Fig 12, a).

Operation was performed on February 12, 1936. The entire mass was carefully resected, including the metacarpal head. The base was not resected, but was excavated to receive a metacarpal shaped, measured graft from the tibia. The pathologist reported fibroma of bone. The patient made an uneventful recovery with almost complete return of form and function. The smooth graft eventually developed the contours of a metacarpal bone, including a narrow cavity (Fig 12, d).

CASE 10. Y. B., aged 22 years, Michael Reese Hospital. There was a history of pain and limp in the left knee beginning several months prior to observation at Mandel Clinic. Roentgenograms made November 29, 1941 showed an expanding lesion of the medial condyle of the left femur (Fig 13, a and b). The patient was operated upon several weeks later at which time frozen section biopsy by Dr Otto Saphier confirmed the clinical diagnosis of benign giant cell tumor. Through an adequate window, the contents of the tumor mass were completely resected, curetted, aspirated, irrigated, fulgurated with the Brill electrode endotherm, and packed with long tibial struts and cancellous bone grafts. A long plaster of paris spica was applied. Subsequent roentgenograms showed reconstruction of the medial condyle and proliferation of the grafts. After the

cast was removed 3 months postoperatively, a walking caliper brace was applied for 9 months. With physical therapy, the patient obtained a 90 degree range of painless motion with excellent stability.

TRANSVERSE INCISION FOR PYLOROMYOTOMY

JOHN L. KEELEY, M.D., F.A.C.S., Chicago, Illinois

THE surgical management of infants with hypertrophic pyloric stenosis is now well standardized and highly successful. Its low mortality has been brought about by two factors. One is the introduction of the operation of dividing the muscular fibers of the pylorus longitudinally as is practiced universally at present, this operation having been developed by Frédet (6), Weber, and Rammstedt. Almost immediately following the introduction of this operative procedure the mortality figures improved. This less formidable operation brought about the results which had formerly been attained only by such a procedure as gastroenterostomy, a serious operation in the first few weeks of life. The other factor is one that developed more gradually, that is the improvement in preoperative and postoperative care. No longer are these patients operated upon as emergencies. Dehydration, acidosis, anemia, and avitaminosis are corrected prior to surgery. Postoperatively the prompt resumption of feeding, and careful attention to caloric needs and fluid balance have further improved the results. In fact, series of cases numbering 310 (Donovan, 5), 225 (Ladd, 12), 172 (Schaefer and Erbes), and 167 (Strauss) have been operated upon without a death. The mortality in complete series reported by these authors is 0.24 per cent (Donovan), 0.9 per cent (Ladd), 3.8 per cent (Schaefer and Erbes), and 2 per cent (Strauss). The average mortality figures in the reports collected and summarized by Szilagyi and McGraw, however, was 7.9 per cent. These reports covered the years 1923 to 1941 but, as in most studies, there has been a steady decrease in the mortality in more recent years due to increasing experience with the operation and improvement in the preoperative and postoperative management. Currently, immediate satisfactory results may be anticipated in 97 to 98 per cent of the operative cases with a rate for reoperation of 2 to 3 per cent and an average mortality figure of between 1 and 2 per cent (22).

Nevertheless, wound disruption continues to be a serious, though infrequent, complication and has accounted for fatalities in some series. Ladd (10) ascribed 3 deaths in his series to evisceration. Two patients in another series by the same author and his associates (12) suffered dehiscence of the wound but re-suturing was successful. In the series of 84 cases from Cook County Children's Hospital studied by Oberhelman, disruption of the wound occurred twice with fatal outcome in both instances. Donovan (3) reported 3 instances in 119 cases. Schaefer and Erbes reported 4 dehiscences of which 1 was fatal. It has long been understood that very careful closure of the abdominal wall in these cases is necessary. This has been emphasized by Ladd and Gross (11) who point out that usually the abdominal wall is only $\frac{1}{8}$ to $\frac{3}{16}$ inch thick (3 to 5 mm). The well established type of incision is a vertical one through the right rectus muscle beginning at the costal margin and made deliberately over the liver so that the liver will form a barricade against the wedge effect of the omentum and other smaller structures when the incision is closed. The rectus muscle is either split or retracted laterally before the posterior rectus sheath and the peritoneum are opened vertically. In either case, a certain number of wound disruptions have occurred with this incision.

That this vertical type of incision is not uniformly satisfactory is indicated by the variety of other incisions recommended. Thus, Robertson advocated a gridiron incision made lateral to the rectus muscle and below the costal margin. This incision, while separating structures of the abdominal wall according to their lines of cleavage and direction of fibers, has all of the advantages of the McBurney incision in that respect. However, it is located at a point where delivery of the pyloric tumor

Fig 3 Closure of the transverse incision

Fig 1 Incision is made at level of previously palpated pyloric tumor. Note how pylorus fills the incision preventing extrusion of other structures

through the incision is not always easy, and many times considerable trauma to the stomach, the omentum, and perhaps to the transverse colon may result from attempts to deliver the pyloric tumor

Much has been written concerning the advantages of transverse incisions (7, 8, 16, 18), and it is generally conceded that with them (a) the tension in the area of the incision is principally parallel to the incision itself, (b) there is less wound disruption, and (c) patients are much more comfortable. The first two of these advantages have apparently prompted the use of many modifications of this type of

incision in the surgical treatment of hypertrophic pyloric stenosis. Thus Davis described an incision which is transverse through all the layers of the abdominal wall except the rectus muscle which is split vertically. Meredith described an incision vertical through all layers except the posterior rectus sheath and peritoneum which were divided transversely. The rectus muscle was split. Brunkow advocated a high right rectus transverse incision. Singleton, in discussing Robertson's paper, described the incision he favored. It is essentially the same as Meredith's, and he emphasized that with the transverse incision there was no room for evisceration of omentum and bowel. Horgan pointed out the advantages of a high transverse incision through all layers of the

Fig 2 Diagrammatic presentation showing method of delivery of pyloric tumor through small incision. Down

ward pressure on abdominal wall makes excessive traction on pyloric attachments unnecessary

abdominal wall except the rectus muscle which is dissected from the anterior rectus sheath and retracted medially.

It is true that most of the infants with hypertrophic pyloric stenosis will do well regardless of the type of incision, their general condition being favorable to adequate wound healing. However, in the poor risk patients, many of which are operated upon under local anesthesia, the type of incision which is least liable to undergo dehiscence is desirable.

The transverse incision recommended here is approximately 4 centimeters long, divides all layers including the right rectus muscle transversely, and may be located anywhere from just below the costal margin down to the level of the umbilicus (Fig. 1A) depending upon the point at which the pyloric tumor has been palpated prior to operation. The incision need not be longer since in typical cases properly investigated, there should be very little if any doubt about the diagnosis, therefore, no need for any but regional exploration. In rare instances in which the diagnosis is uncertain, it may be verified at operation by the introduction of one finger into the abdomen.

All intra-abdominal manipulations are done with instruments, principally Babcock forceps and tissue forceps without teeth. Since the incision is made at a level which corresponds to the location of the pyloric tumor, the first structures encountered may be the edge of the liver or the anterior wall of the stomach. With the body and the fundus of the stomach collapsed, due to the presence of an intussusception in the stomach, it is possible to pass the wall of the stomach to the left and by doing so the pylorus can be brought to a point just underlying the incision.

It is not necessary to bring any structure except the pylorus outside the abdomen (Figs. 1B, 1C). Since the average dimensions of the pyloric tumor are approximately 2 centimeters in length and about 1.5 to 2 centimeters in diameter with a wall 5 to 8 centimeter thick (22) there should be no difficulty in delivering the pyloric tumor through the transverse incision. The gastric end of the tumor is brought up first as shown in Figure 2B. In this way, a pyloric tumor even longer than the incision may be brought outside the abdominal wall

(Fig. 2C). Since the incision is usually made at some distance from the costal margin it is possible to press down on the anterior abdominal wall and thus allow the tumor to be delivered outside the abdominal wall without excessive traction on the attachments of the pyloric area. As some of the bleeding in this divulsion is thought to be due to traction on the attachments of the pyloric area with resulting interference with venous return, there may be less difficulty with hemostasis. At this point, it may be noticed that the pyloric tumor, lying transversely and being brought up through the transverse incision, closes off practically all of the incision (Fig. 1B) and leaves no room above or below the pylorus for the herniation of omentum or small bowel such as frequently happens in the vertical incisions.

The divulsion or division of the circular fibers of the pylorus is then done in the usual manner with precautions against perforating the duodenal mucosa but with care that all fibers are divided sufficiently to a point where the normal thickness of the seromuscular layers of duodenum and the stomach is reached. A binocular loupe or other visual aid may be used, not so much to insure the division of every single muscle fiber, but rather to guard against perforation of the duodenal mucosa. Robertson believes that squeezing the duodenal end of the tumor between the left index finger and left thumb causes a change in the relationship of the muscle mass to the duodenal mucosa so that splitting the muscle mass can be accomplished with less danger of perforating the duodenal mucosa.

The closure of the wound is easy (Fig. 3). The edges of the posterior rectus sheath and peritoneum can be approximated easily even if the patient is straining. This is certainly not the case when these layers have been divided vertically. The rectus muscle is sufficiently adherent to the anterior rectus sheath to prevent marked retraction. However, approximation of the rectus muscle is indicated because it obliterates any dead space which might otherwise result and in which serum might collect. This can be accomplished by means of X sutures of fine chromic catgut or by catching the muscle edges in the fascial sutures. The closure of the rectus sheath is ac-

complished by means of interrupted X sutures of fine silk and the subcutaneous tissue and the skin are approximated with fine catgut and silk respectively

It is agreed that the cosmetic result is of minor importance. Even the vertical incision with broadening of the scar becomes proportionately less conspicuous as the child grows. However, with the transverse incision, after 2 or 3 months, it may be difficult to see the incision except upon very close inspection in good light. The incision as described herein has been used in a series of 34 personal cases with no instance of wound disruption.

SUMMARY

Various abdominal incisions used in the surgical treatment of congenital hypertrophic pyloric stenosis are presented. A transverse incision through all the layers of the abdominal wall including the right rectus muscle and at the level of the previously palpated pyloric tumor is described and discussed in detail. It has been entirely satisfactory in a series of 34 of the author's cases.

The Anatomy of the Hernial Regions II Femoral Hernia —
 Barry I. Aronson, Arthur F. Keimann, and La Vern I. Saigart

THE ANATOMY OF HERNIAL REGIONS

II Femoral Hernia

BARRY J ANSON, Ph D (Med Sci), ARTHUR F REIMANN, M D, and
LA VERN L SWIGART, M D, Chicago, Illinois

CONTINUING a report upon their study of the anatomy of the important hernial regions, the authors will herein record their dissection-experience with the strata which, passing from abdomen to pelvis, converge upon the large vessels in the proximal part of the thigh and form sheaths for the femoral artery and vein

MATERIAL AND METHODS

For the present account the authors depend chiefly upon three particularly favorable specimens, each of them a well developed adult. Two male cadavers were employed to illustrate the normal anatomical relationships of structures of the inguinal wall, pelvic cavity, and proximal thigh (Figs 2a and 2b, 3a to 3d), a female specimen was utilized for drawings of the same structures, as affected by a femoral hernia (Figs 4a and 4b, 5a and 5b, 6a to 6c). In order to record pertinent morphology of the region where a femoral hernia reaches a subcutaneous, palpable posi-

tion, variations in the fossa ovalis and its vascular contents are pictured (Figs 1a to 1f), and statistical data are presented

OBSERVATIONS AND DISCUSSION

In contrast to the movable, and often pedunculated, indirect inguinal hernia, the mass of a femoral hernia appears to be little more than a swelling in the upper and inner angle of the femoral (Scarpa's) triangle. Here it is usually situated below and to the side of the pubic tubercle and below the inguinal ligament, however, sometimes the upper part of the mass may extend above the ligament.

In descending from an abdominal to a femoral position, under the ligamentous edge of the external oblique and upon the superior pubic ramus, a herniating mass (intestinal or omental) pushes ahead of it the deeper layers of inguinal position to a point where, in or beyond the fossa ovalis, the hernia acquires additional coverings from the overlying layers of the thigh. Having reached subfascial level in the thigh, the hernia elevates the overlying skin

Contribution No. 504 from the Anatomical Laboratory of Northwestern University Medical School

Figs 3a to 3d. Structures related to the regions of inguinal femoral and obturator herniae. Specimen II. Fig 3a. The abdominal layers have been incised along the inguinal ligament, the peritoneum (at 1), with the coils of small intestine, has been lifted to show the preperitoneal connective tissue (at 2). The sites of inguinal and femoral herniation are indicated by arrows A and B, respectively. The site of the orifice of the abdominal inguinal ring is marked by a circle. The fascia lata has been reflected to expose the sartorius muscle, as the latter forms the lateral boundary of the femoral triangle. The preperitoneal (subserous) layer (indicated by **) is carried downward from the iliac vessels upon their femoral continuations (at *), from these larger vessels arise the deep circumflex iliac and the inferior epigastric branches (unlabeled), from lateral and medial sides, respectively. Fig 3b. The femoral sheath of the opposite thigh has been opened to show the femoral vein, the vessel has been retracted in order to demonstrate the manner in which its tributaries are invested by tubular continuations of the sheath. Fig 3c. The vein has been removed to demonstrate similar relations of the corresponding artery. Fig 3d. Anterolateral portion of a pelvis, viewed from within, sagittal section to

the left of the midline. Specimen III. The viscera and subserous tissue have been removed, the external iliac vessels have been cut and lifted in order to emphasize the tubular character of the vascular lacuna. Medial to the vein is the femoral ring (at arrow B). Vessels converge upon the internal orifice of the obturator canal (arrow C). The iliacus and psoas muscles and the femoral nerve occupy the muscular lacuna.

An indirect inguinal hernia would transverse the inguinal canal in indirect course, from the abdominal orifice (encircled by the ring), through the subcutaneous fault in the fibers of the external oblique aponeurosis (at arrow 4, Fig 3a, between the crura of the ring) to some point beyond the aponeurotic hiatus. Its immediate investment would be the peritoneum, which, as a vaginal process, would be progressively dilated as herniation progressed (see article I). A femoral hernia would, in a more direct course, pass beneath the inguinal ligament upon the pecten of the pubis and between the lacunar ligament medially and the femoral vein laterally (at arrows B, Fig 3a and Fig 3b). An obturator hernia would enter the internal orifice of the obturator canal (Fig 3d, at arrow C). The further course of an obturator hernia is pictured in article III.

Figs 1a to 1f Variations in form, size, and contents of the fossa ovalis. Examples arranged in the order of increasing dimensions, from the smallest to the largest encountered in a series of 200 lower extremities. All are examples of the left thigh. In the specimens shown in Figures 1a and 1e, the femoral artery is but slightly exposed to the side of the femoral vein, in those depicted in Figures 1c and 1d the artery is wholly concealed beneath the falciform margin of the fossa, in those illustrated by Figures 1b and 1f it is fully exposed, in the former instance overlying the point of termination of the saphenous vein in the femoral. Abbreviations: *Vc1s*, Vena circumflexa ilium superficialis, *Ves*, Vena epigastrica superficialis, *Vpe*, Vena pudenda externa, *Vsm*, Vena saphena magna. The unlabeled vessel, ascending near the great saphenous vein, is the accessory saphenous vein.

Before considering these layers in detail, as evidenced in the selected case of femoral hernia (Figs 4 to 6), it may be profitable to review their disposition in relation to such a hernial protrusion, that is, as elements which guide the hernia in its descent and as structures to which the hernia becomes secondarily related.

At the termination of its migration from the abdominal cavity into the thigh, the hernia attains subcutaneous position at the fossa ovalis (saphenous opening), where the degree of its prominence depends chiefly upon the dimensions of the fossa and upon the extent

of its occupancy by blood vessels (Figs 1a to 1f). In order to reach the thigh, the hernia is obliged to pass beneath the inguinal ligament, which, through its nearness to the resistant superior pubic ramus, constitutes a temporary hindrance to its descent (Figs 2a, 2b, and 3a, at arrows *B*). The hernia emerges beneath the superior horn (cornu) of the fossa's falciform margin (compare Fig 1e), resting upon the fascial covering of the pectineus muscle (Figs 2a and 2b), in so doing, it has traversed the vascular lacuna of the subligamentous space, occupying the "space" medial to the femoral vein (Fig 2b). Space exists,

Figs 2a and 2b Two stages in the dissection of spaces and contained structures in the inguofemoral region Specimen I Fig 2a The superficial fascia has been removed, exposing in the inguinal and proximal femoral regions, respectively, the aponeurosis of the external oblique muscle and the fascial investment (fascia lata) of the muscles of the thigh The external spermatic fascia has been removed in order to expose the spermatic cord and the crural boundaries of the subcutaneous inguinal ring The femoral vessels have been excised from the fossa ovalis (saphenous opening) The course of a femoral hernia is indicated by the arrow B, which here emerges from the femoral ring Distal to the fossa ovalis an artificial window has been cut in the fascia lata to demonstrate the further course of the femoral vessels (transected) A similar opening has been made in the fascia, lateral to the fossa ovalis into the space of the muscular lacuna, from which latter the iliopectineus muscle has been removed, but in which

the femoral nerve remains intact Fig 2b The investing sleeves of the fascia have been cut away in such a manner as to reveal the muscles and associated structures which bound the femoral triangle Marginally, the triangular space is bounded by the sartorius and adductor longus muscles, the floor is formed in part by the pectineus muscle The iliopectineus, removed from the muscular lacuna together with the subjacent portion of the articular capsule, would form the floor of the space laterally The roof is the inguinal ligament The stumps of the transected femoral vessels remain in the vascular lacuna The small orifice situated on the medial aspect of the femoral vein is the femoral ring through which a hernia would pass from the abdomen into the thigh in the direction of the arrow B, to occupy the fossa ovalis The hernia would be surrounded by the lamellae of the femoral sheath and would lie beneath the superficial fascia (see following dissections continued in specimen II)

of course, only after investing tissues, related to the blood vessels, have been removed. These tissues form coverings for the vessels, and would likewise invest a neighboring hernia, in the most medial of the three spaces of the vascular lacuna. This medial space is the femoral canal, its orifice beneath the inguinal ligament is the femoral ring.

The two investments of a femoral hernia are derived from abdominopelvic layers. The outer layer is a femoral prolongation of the fascial coverings of parietal muscles, namely, transversus abdominis and iliopsoas (Fig 3d). They are carried outward to ensheath the femoral continuations of the external iliac vessels and as the wall of the femoral canal (arrow *B* in Fig 3d). The inner coat is a derivative of the retroperitoneal (subserous) layer of the abdomen and pelvis (** in Fig 3a, removed in Fig 3d).

Internal to the subserous layer, in the abdomen and pelvis, is the peritoneum (freed and lifted in Fig 3a). It would be the immediate covering of the herniating intestine or omentum.

Obviously, then, as a hernial protuberance is exposed by incision through the skin it consists of the following from without inward: the superficial fascia of the thigh, with contained vessels and nerves, the outer femoral sheath (from the internal investing fascia of the abdominal and pelvic musculature), the inner sheath (from the retroperitoneal layer), the serous coat (as a diverticular process of the peritoneum over the femoral ring), space (continuous with that of the peritoneal cavity), the hernia itself.

The several layers, their thickened portions and the orifices, or faults within them, will now be considered from without inward, in the order in which they would be encountered in dissection.

1 *Skin and superficial fascia* The outer layer of superficial fascia of the abdomen (Camper's layer) is continued downward into the thigh, over the inguinal ligament. It contains moderately large lobules of fat and vessels of small size. In the region where the hernial mass protrudes the layer of superficial fascia is thinned and the fatty tissue almost disappears.

The deep layer of superficial fascia in the inguinal region is a membranous sheet, irregularly bound down to the subjacent fascia of the external oblique muscle. This layer (Scarpa's fascia) finds a firm attachment along a line just below and parallel to the inguinal ligament and, thereby, to the fascia lata. Distal to the level of the ligament, Scarpa's layer immediately thickens to accommodate a considerable quantity of fatty tissue, superficial arteries and veins, and lymphatic vessels and glands. The thickened portion of the deep layer extends downward for a distance of a few centimeters beyond the inguinal ligament. Laterally, medially, and inferiorly, beyond the boundaries of the femoral triangle, the layer thins to become indistinguishable from a fatty pannicle. The inguinal lymph glands, the main portions of the superficial arteries and veins, emanating from and converging upon the fossa ovalis, lie chiefly within this deeper lamella.

Since the hernial mass regularly gains an external position by issuing through the upper part of the fossa ovalis, it must here encounter the deep layer of the superficial fascia. As the hernia increases in size, its shape and position are seemingly determined by the firm marginal attachments of the layer, and by its contents (see hereinafter).

2 *Fascia lata and fossa ovalis* The thick sheath (fascia lata) for the muscles of the thigh is aponeurotic rather than fascial. It is anchored to the inguinal ligament, and, indirectly, to the underlying iliopsoas muscle-fascia, since the latter gives partial origin to the inguinal ligament (Figs 1a to 1f).

The oval defect in this investing sleeve, namely, the fossa ovalis, is so placed that medially and superiorly a narrowed strip, a so called superior cornu, is formed. The cornu is carried inferomedialward, in a falciform margin, to become continuous with the pectineal fascia on the floor of the fossa, and with the lacunar extension of the inguinal ligament. In being so disposed, the free edge of the superior cornu completely hides the lacunar ligament in external view. The superior cornu in being prolonged downward as a falciform margin of the fossa, ends medially in an inferior cornu. The inferior cornu, then

Figs 4a and 4b. Abdominal contents in a case of femoral hernia in a female cadaver. Specimen IV. Fig 4a. The omentum, with the transverse colon at its distal margin, forms an apron which almost completely obscures the coils of intestine. On the left side the omentum is locally fastened by a narrow band (along broken line) to the abdominal wall over the roof of the femoral canal. A nodule

of the omentum occupies the femoral canal (orifice of the latter, 1 cm in diameter). Fig 4b. The hernial mass, removed from the femoral canal, has been turned upward to demonstrate its form and size. Prior to the time when removal was accomplished the omentum was cut (at arrows) from the area of anterior fixation to the parietal peritoneum (see Fig 4a).

sweeping upward, becomes continuous with the pectineal fascia on the floor of the fossa. The pectineal part lies at a deeper level than the more lateral and superior portions. Behind the femoral vessels it ascends, for attachment, to the superior ramus of the pubis, covering the pectineus muscle as it does so. The difference in level between the superior cornu of the fossa and the upper attachments of pectineal fascia accounts for the depth of the vascular lacuna which, in transmitting the femoral artery and vein, contains a com-

partment for each of these vessels as well as a third space, termed the femoral canal (Figs 2a and 2b at arrows B). It is in the last-named division of the lacuna that the neck of a femoral hernia sac is encountered.

Based upon a study of 200 specimens, variations in form and size of the fossa ovalis may be described and figured. In outline, the fossa is occasionally almost circular (Fig 1a). Usually, however, it is oval (Fig 1d), when thus compressed laterally, the long axis may be placed vertically (Fig 1c), or ob-

liquely (Fig 1e) Occasionally the fossa is dart-shaped, with the pointed end directed downward (Fig 1f)

The relationship between the superior cornu and the inguinal ligament is inconstant. It is conventionally described as being attached above to the medial half of the inguinal ligament. When the fossa is proximally placed in the thigh, the superior horn appears to be a derivative of the inguinal ligament (Fig 1b), the ligament itself seeming to serve as one boundary of the fossa. Its independence in other instances is equally striking, an appreciable distance often intervening between the ligament and the cornu (Figs 1a, 1c to 1f)

Within the space of the fossa accessory hiatuses not infrequently occur, transmitting tributary veins from muscles to the femoral vein. These appear in simple form (Fig 1c) or as multiple orifices (Fig 1d)

In size the greatest variability is encountered. The smallest fossa in the 200 specimens is 1.6 centimeters in length, 1.7 centimeters in width, the narrowest measures 1.0 centimeter, the shortest, 1.6 centimeters. The largest fossa in the group is 8.5 centimeters in length, 3.5 centimeters in width, the widest measures 6.4 centimeters, the longest, 8.5 centimeters. Ninety per cent of the specimens (180 fossae) measure between 3.0 centimeters and 6.4 centimeters in length, 53.5 per cent (107 fossae) measure between 3.5 centimeters and 5.4 centimeters. The average length is 4.6 centimeters. In width, 87 per cent (174 fossae) are between 1.5 centimeters and 3.9 centimeters, 70.5 per cent (141 fossae) are between 2.0 centimeters and 3.9 centimeters.

Without exception fossae are capacious orifices for the vessels which they transmit, in only one case does the circumference of the saphenous vein approach that of the fossa through which it passes, regularly a very considerable space, unoccupied by vessels, is included between the cornua of the fossa (e.g., Figs 1c to 1f), the size of contents in no way affecting the proportions of the orifice. So ample, in fact, is the space of the fossa, that the contained femoral vein is almost invariably exposed throughout its width. Moreover, in 83 per cent of 100 consecutive cases

the femoral artery, also, is wholly or partially exposed. More specifically, in 36 per cent, three-fourths to all of its breadth is in view (Fig 1e), in 30 per cent, one-half to one-fourth, in 17 per cent, not only is the artery entirely in view, but space occurs laterally, unoccupied by vessels (Fig 1b).¹ It might be safely assumed that capaciousness of space would render hernial migration easier.

In the hernial specimen illustrated, the fossa is elongate (Figs 5a and 5b). The neck of the hernial sac impinges medially upon the free edge of the superior cornu. Behind, it rests upon pectineal fascia. The hernia thus lies anterior to the confluence of saphenous and femoral veins in the fossa ovalis, superficial veins enter the saphenous behind and below the body sac, the external pudendal vessels course across the fossa ovalis below the sac, while the superficial epigastric artery ascends from the region of the fossa lateral thereto (Fig 5b). Superficial lymphatics which ascend from the lower extremity and from adjacent lymph glands pass into the vascular lacuna posterior to the body and neck of the sac.

3 *External femoral sheath.* At the inguino-pelvic interval, a space, the vascular lacuna, permits egress of the external iliac vessels from the pelvis into the thigh. The orifice thus produced is an elongate oval with its long axis in transverse plane. The lacunar ligament, the inguinal ligament, the iliopectineal muscle, and the superior ramus of the pubis form the resistant boundaries of the orifice. Internal to these structures the iliac fascia (transversalis fascia), are carried in a femoral direction around the margins of the orifice, to produce an infundibuliform investment for the femoral vessels. Anteriorly and medially this fascial funnel is supported from without by the lowermost aponeuroticofascial portions of the transverse abdominal and internal oblique muscles. These strata arise partly from the medial edge of the iliopectineal fascia in common with the inguinal ligament,

¹ The venous channels which converge upon the terminal segment of the great saphenous vein are highly variable. They have been described and figured in an article (based upon 550 specimens) by the present author and his colleagues in an earlier issue of this journal (1946 82 52-63)

Figs 5a and 5b The femoral hernia, in relation to the external fascial and aponeurotic layers of the inguinal and proximal femoral regions (same specimen) Fig 5a The superficial fascia has been removed except in the territory of the hernia and in the pudendal area medial thereto. The aponeurosis of the external oblique muscle and the fascia lata are shown. The fossa ovalis in the latter layer is exposed (for purposes of topography) in its lower part, that is, over the inferior horn of the falciform margin. The hernia produces a circular bulging in the overlying

superficial fascia. In this fascia the superficial veins (pudendal, epigastric, circumflex iliac) descend to join the saphenous. Fig 5b The hernial sac in relation to the superficial veins and the falciform margin of the fossa ovalis. The superficial fascia has been removed from the hernial sac to reveal the latter's outline, a gland of the superficial subinguinal group, and the superficial veins. The veins form a basket-like support for the hernia, the latter being pressed upward against the inguinal ligament, not downward over the inferior cornu of the fossa.

they arch over the femoral vessels and gain a strong medial anchorage by their insertion into the pecten of the pubis behind the lacunar ligament. Thus the femoral sheath anteriorly is a fascial prolongation of the intermediate and innermost of the three muscle strata of the abdomen. Both medially and laterally at the femoral orifice the anterior part of the femoral sheath is continuous

with a posterior component which consists of the iliopectineal fascia. While the lateral wall of the funnel-shaped femoral sheath is almost vertical, the medial wall describes a moderate curve, the concavity of which is directed medialward (see esp Fig 6b). Owing to the obliquity of the medial wall, as it extends from behind the lacunar ligament to reach the medial surface of the femoral vein, there exists

SURGERY, GYNECOLOGY AND OBSTETRICS

Figs 6a to 6c The hernial sac, its composition and inguino-femoral continuities (same specimen) Fig 6a The aponeurosis of the external oblique muscle has been reflected with it the fascia lata has been turned aside after cutting vertically through the superior cornu of the fossa ovalis. The lateral wall of the hernial sac has been cut away. In this way the following features are demonstrated the laminar nature of the hernial sac derived in part from the femoral sheath the relation of the orifice (at arrow) to the part of the sheath which invests the femoral vessels the form and position of the sheath The sac is composed of three layers namely the fascia of the abdominal and pelvic muscles the subserous connective tissue and the peritoneum The femoral sheath is made up of the outer and intermediate of these three layers Fig 6b The orifice of the hernial sac in relation to the deep inguinal and femoral structures The sac has been transected at its neck the internal oblique muscle has been turned aside to expose the subjacent transversus abdominis As the sac passes through the femoral canal it is bounded medially by the lacunar ligament (here cut

and turned downward) laterally by the portion of the femoral sheath which transmits the femoral vein, superiorly by the lower margins of the three lateral abdominal muscles, and inferiorly by the superior ramus of the pubis (covered by the pectineus muscle and the pectineal fascia) The outer lamella of the femoral sheath is made up of the fascial coverings of the transversus and iliopsoas muscles prolonged into the thigh Its surface (here exposed) is irregular, owing to the presence of fat in the contiguous layer of connective tissue The latter, carried into the thigh as an extension of preperitoneal tissue in the pelvis, forms the internal layer of the femoral sheath and immediately surrounds the vessels (exposed in Fig 6c) Fig 6c The compartments of the femoral sheath, their investments contents and interrelationship The hernial sac in front its constituent layers demonstrated by carrying the incision vertically upward through the deep layers of the inguinal wall Its space (traversed by arrow B) is continuous with that of the peritoneal cavity The hi

(Legend continued on opposite page)

a small, conical space within the sheath adjacent to the femoral vein. The base of the cone lies over the pubic pecten, the opening into the space is the femoral ring.

The lower aponeurotic and fascial portions of the internal oblique and transverse abdominal muscles cover the internal surface of the lacunar ligament by inserting into the pecten of the pubis, they form the immediate boundary for the femoral ring on its medial aspect. This "internal lacunar ligament" is strengthened by a flattened, aponeurotic, lateral expansion of the rectus tendon, which is fastened, with the transversus aponeurosis, to the superior pubic (Cooper's) ligament. The rectus margin is variable, since the tendon may be wide or narrow.

In the hernial specimens, while the anterior femoral sheath remains intact over the vessels, that part of the sheath once enclosing the canal medial to the femoral vein is greatly distended to form a thin envelope for the body and neck of the hernia (Figs 6a to 6c). Since anteriorly the femoral sheath is made up of fascial continuities derived from the intermediate and deep muscular layers of the inguinal wall, the lowermost portions of these layers form an arch over the neck of the sac, strong when the layers are muscular or aponeurotic (Figs 6a and 6b), weak when they are fascial. Posteriorly the femoral ring possesses, for firmer support, a wall consisting of the pectineus muscle and its investing fascia, and the superior ramus of the pubis (Fig 6c, compare Figs 3a and 3d). Laterally the neck of the sac is related to the femoral vein (Figs 6b and 6c, compare Figs 3a and 3b), separated therefrom by a thin cushion of adipose tissue in which are lodged lymphatic vessels.

4 *Internal femoral sheath and preperitoneal connective tissue* The covering of the femoral vessels which is, as just described, derived from abdominal and pelvic fasciae, constitutes the femoral sheath of all regular, and therefore, familiar, textbook accounts. Ac-

tually, the vessels are imbedded in fatty connective tissue, which provides for them a second, or internal, femoral sheath. This matrix is directly continuous with the preperitoneal tissue layer of the abdomen, it surrounds, and passes as septal walls between, the femoral artery and vein, it fills the conical femoral canal (Figs 3a to 3c), and conveys lymphatic channels from the inguinal to the iliac lymph glands.

As seen from the abdominal aspect, the external iliac vessels course toward the lateral and intermediate portions of the vascular lacuna (Fig 6c, compare Figs 2b and 3a). The femoral canal, in the medial part of the lacuna, is normally filled with fatty preperitoneal (retroperitoneal, subserous) connective tissue. This tissue conceals the pelvic opening or "ring" of the femoral canal, but leaves a concave depression on which the femoral neum rests. This concavity is the femoral fossa. It is this point at which a hernia internally presses the peritoneum into the subperitoneal femoral ring. In specimens of femoral hernia this preperitoneal layer forms an important envelope for the hernial process (Figs 6a to 6c).

In the preperitoneal connective tissue of the lower abdominal wall the inferior epigastric vessels course obliquely from the femoral sheath to the rectus muscle (Fig 3a). However, an anomalous branch, the obturator artery, in approximately 30 per cent of cases, descends medially, in arciform course, close to the femoral ring. The umbilical artery passes upward in the lateral umbilical fold 0.5 to 1.0 centimeter medial to the femoral ring. Supposedly obliterated, this vessel sends small branches forward, beside the urinary bladder, they pass over the pubic pecten and into the femoral ring, to form an additional supply for the tissue within and about the femoral canal.

5 *Peritoneum* A slight peritoneal depression, or femoral fossa, marks the site of the femoral ring. It is critically located at the abdominopelvic junction. This small fovea in the serous layer rests below upon the rounded margin of the pubic pecten and the origin of the pectineus muscle. Medially is situated the lateral umbilical fold—a fairly tall plica

laminar sheath, which houses the femoral vessels, has been opened to demonstrate the continuity of its strata with those of the abdomen. The hernial sac is thus a diverticulum of the parietal peritoneum which, covered by subserous and fascial coats, presses outward through the vascular lacuna beneath the inguinal ligament to occupy a once "empty" compartment of the femoral sheath.

in the majority of cases Laterally lies the peritoneal elevation for the epigastric vessels, usually this fold is low The femoral fossa, therefore, lies at the inferomedial edge of the medial inguinal fossa, and is so placed as to be the apex of a broad peritoneal funnel, toward which apical point the vertical wall of the lateral umbilical fold might assist in directing a mobile viscus or a portion of the omentum The peritoneum which forms the femoral fossa, together with the subjacent preperitoneal tissue, becomes protuberant over the herniating mass (Fig 6a) External to the subserous coat is the fascial envelope derived from the transversus abdominis and iliopsoas muscles (Figs 6a to 6c, compare Fig 3a, layer marked 3) This outer coat is the femoral sheath of familiar descriptions (the inner, subserous investment customarily being disregarded) In further excursion, a portion of jejunioileum, or of omentum (Figs 4a and 4b), descending through the superficial fascia of the thigh (Figs 5a and 5b), this pannicle becomes a hernial coat as soon as the hernia reaches the fossa ovalis Thereupon, the hernia acquires relationships to superficial blood vessels, lymphatics, and cutaneous nerves regularly present in the superficial fascia of the femoral triangle and in the corresponding stratum of the inguinal region (Figs 5a and 5b, 1a to 1f) The veins which converge upon the saphenous and femoral may, apparently, be instrumental in directing the hernia cranialward, over the inguinal ligament (Fig 5a) In the specimen illustrated, the course was initially downward and forward (Figs 6b and 6c, arrows B), then somewhat upward (Figs 5a and 5b)

The solidity of the floor beneath the femoral ring is another feature of anatomical and surgical significance Outside the peritoneum and preperitoneal connective tissue lies the bony ridge of the pubic pecten From this ridge the superior surface of the pubic bone slopes slightly downward and forward, covered at the more distal portion by the peritoneal fascia and muscle It is this declinated surface which forms the actual floor of the ring and canal, and, therefore, a guide for the hernia in the first stage of its emergence

CONCLUSIONS

On the internal aspect, the abdominal wall presents an oval fovea corresponding in position to the femoral ring Here, as elsewhere, the peritoneum of the fovea rests upon a stratum of connective, the preperitoneal, tissue Externally, both on the abdomen and in the proximal thigh, the superficial fascia is bilaminar in character The deeper portion is locally thickened through inclusion of fat, subcutaneous vessels and lymph glands As the subserous tissue is prolonged upon the femoral continuations of the external iliac vessels, it is in turn covered by fascia derived from the parietal musculature These are, respectively, inner and outer lamellae of the femoral sheath They are carried downward through the vascular lacuna (beneath the inguinal ligament), to lie deep to the superficial fascia of the thigh where the fault in the investing fascia (fascia lata) brings them into contact The same relations are acquired by any herniating mass which, coming to occupy the most medially situated space in the femoral sheath—namely, the femoral canal—passes in succession through the femoral ring, femoral canal and fossa ovalis, to subcutaneous position

The pathway taken by a femoral hernia, then, must be at first almost directly downward into the femoral fossa, declination of the superior surface of the pubic bone carrying the process forward through the femoral ring The herniating structures meet a restraining arch of aponeurotic fibers formed by that part of the femoral sheath which is securely attached to the pubic pecten Further resistance is offered by the lacunar ligament But within the vascular lacuna the femoral vein and the investing sheath constitute a resilient lateral wall Further progress distalward brings the process into the lower reaches of the femoral canal, where it impinges upon the overlying superior cornu of the fossa ovalis After passing this point, the process is suddenly relieved of anterior constriction, and can press toward the integument in angulated course While the neck of the process must remain small in size, the distal mass of the tumor may thus increase in bulk In this situation, carrying the bilaminar femoral

sheath forward as a conjoined envelope, the hernia impinges upon the deep layer of the superficial fascia as the latter locally covers the fossa ovalis. Further descent is seemingly hindered by the basket-like arrangement of vessels related to the fossa, and by marginal fixation of the cribriform layer. The hernia consequently presses superiorly in front of the falciform margin and over the inguinal ligament.

Considering anterior hernial orifices together, the femoral canal (with the ring) represents an anatomical arrangement standing between inguinal and obturator canals in point of structural weakness.

Tendency toward hernial protrusion through the inguinal wall is greatly increased by the presence of a congenital serous sac, and by subjection to the trauma and intra-

abdominal pressure against parietes which are distensible. The femoral orifice is a narrow one, encircled in front by an aponeurotic arch, bounded by the lacunar ligament medially, and supported behind by a bony ridge. It is weakened only by the existence of potential space in the femoral ring and canal, and by resilience of the large blood vessels on its medial aspect. As will be seen, the obturator orifice, narrower still, is effectively bounded by an osseoligamentous rim, the obturator canal, the canal not only possesses peritoneal, preperitoneal, and ligamentous tissues to support it internally, but also is well barricaded externally by the layered musculature of the thigh.

In a succeeding, and final, paper in this trilogy, the anatomy of obturator hernia will be considered.

OBSERVATIONS ON THE CLOTTING MECHANISM IN MENSTRUATION AND MENORRHAGIA

RICHARD M ELGHAMMER, M D, BURTON J GROSSMAN, M D,
ARTHUR K KOFF, M D, F A C S, PETER V MOULDER, M D,
and J GARROTT ALLEN, M D, F A C S, Chicago, Illinois

IN certain diseases complicated by hemorrhage the whole blood clotting time may be prolonged and an abnormality can be detected by a protamine titration (2). Increases in the protamine titration and whole blood clotting time may occur when all other known hemostatic mechanisms are normal, although usually these changes are associated with some degree of thrombocytopenia (1). Bleeding in such individuals may be temporarily controlled, partially or completely, by the administration of adequate amounts of toluidine blue and protamine sulfate. These agents are known to inhibit heparin and heparin-like substances. The fact that such patients respond to these antiheparin agents (toluidine blue and protamine sulfate) suggests that the clotting defects may resemble that produced by the intravenous injection of commercial beef heparin (3). This comparison, however, may not be valid because certain other endogenous compounds having heparin-like action appear to be chemically different from heparin. Also, it is possible that this physicochemical change only resembles that produced by heparin, and that it is accomplished by a mechanism unrelated to heparin (3).

Menorrhagia was among the bleeding conditions investigated. This study includes coagulation data on 43 patients with menorrhagia, 23 normal female volunteers and 56 normal males.

METHOD OF STUDY

Gynecologic examination of the menorrhagic group was performed by one of us (A K K) and, except for 2 patients who had small uterine fibroids, no gross pelvic disease was found. Biopsies on the first day of menstruation revealed no characteristic endo-

From the Department of Surgery the University of Chicago

metrial pattern. The diagnosis of menorrhagia was based on a history of prolonged profuse menstrual bleeding and anemia. The normal females consisted of volunteers carefully studied with reference to their menstrual history and blood findings. Pelvic examinations were not performed. The group constituting the normal males was composed of medical students and other hospital personnel.

Laboratory studies in both the normal and the menorrhagic groups included the protamine titration (2), whole blood clotting time (4), prothrombin time (5), gross observations for lysis of clots, clot retraction at 1, 6, and 24 hours, and, platelet count. There was no evidence of a blood dyscrasia in any of the patients. The menstrual blood was not examined.

These studies were carried out at different intervals during the menstrual cycle and on the day of heaviest menstrual flow. This usually was the second day of the menstrual bleeding.

Protamine sulfate was administered as single intramuscular injection of 50 milligrams, usually on the day of heaviest flow. Toluidine blue was given orally twice daily for 3 to 4 days in capsules containing 100 milligrams, beginning on the heaviest day of flow.

DATA

Table I presents the results of the protamine titration, the whole blood clotting time, and the group average platelet count in the menorrhagic patients and in the normal female and male groups. The determinations on the menorrhagic group were made during menstrual periods before protamine sulfate or toluidine blue were given.

In Table II are summarized data obtained on patients in the menorrhagic group when protamine sulfate was given intramuscularly.

TABLE I — RESULTS OF THE PROTAMINE TITRATION, THE WHOLE BLOOD CLOTTING TIME AND PLATELET COUNT IN THE MENORRHAGIC AND THE NORMAL GROUP

43 Menorrhagic Patients						
No determinations	When performed	Protamine titration		Whole blood clotting time*		Average platelet counts
		In creased	Normal	In creased	Normal	
106	During profuse menstruation	80	26	67	45	166 000
14	During normal menstruation	3	11	7	7	183 000
82	Intermenstrually	39	43	41	36	193 000
23 Normal Women						
23	During menstruation	5	18	13	10	236 000
35	Intermenstrually	11	24	14	21	211 000
56 Normal Males						
105		3	102	10	95	230 000

*By the technique employed the normal whole blood clotting time ranged from 25 to 35 minutes (4)

or when toluidine blue was administered orally

Gross fibrinolytic activity was noted in only 1 patient. Prothrombin activity was within normal limits in all bloods studied. Prothrombin accelerator factors were not determined.

COMMENT

Several changes referable to the clotting mechanism have been reported for venous blood during the menstrual cycle. Among the changes noted have been a slight increase in the whole blood clotting time (7), a mild to moderate thrombocytopenia (8), and alterations in fibrinolytic activity (6). Many of the patients in our study developed some degree of thrombocytopenia and a slight to moderate increase in the whole blood clotting time during menstruation. These changes occurred also during the intermenstrual period in several members of both the normal and the menorrhagic groups, although less often and less extensively. The increased clotting times were detected only when careful techniques were employed (4).

The abnormality revealed by the protamine titration appeared to be a better index of a systemic hemostatic disturbance in these patients than was either the whole blood clotting time or the platelet count. The protamine ti-

TABLE II — BLOOD STUDIES AND CHARACTER OF MENSTRUATION IN PATIENTS WITH MENORRHAGIA GIVEN PROTAMINE SULFATE OR TOLUIDINE BLUE

Results in 32 patients given protamine†			Studies before administration of protamine			
			Protamine titration		Whole blood clotting time	
Effect*	No. of periods	No. of patients†	Increased	Normal	Increased	Normal
Good	30	25	27	3	19	11
Temporary	5	5	3	2	2	3
None	7	7	3	4	3	4
Results in 12 patients given toluidine blue††			Studies before administration of toluidine blue			
			Increased	Normal	Increased	Normal
Good	7	6	4	3	5	2
Temporary	5	5	4	1	1	4
None	3	3	1	2	0	3

*Good effect—Reversion from profuse to normal menstrual flow for remainder of period.

†Temporary effect—Bleeding slowed 6 to 18 hours; profuse bleeding resumed.

‡No effect—No detectable improvement.

†Seven patients were given protamine sulfate during 2 or more menstrual periods.

††Three patients received oral toluidine blue during 2 or more menstrual periods. Nine patients had received protamine sulfate during previous menstrual periods.

tration was increased in 80 of 106 determinations made during menorrhagic periods. It increased in only 5 of 23 determinations made during menstruation in the women whose menses were considered normal (Table I). When increases in the titration occurred in the latter group, they were less pronounced than those in menorrhagia.

The response of those patients given intramuscular protamine injections correlated fairly well with the status of their protamine titrations at the time the injections were made. Listed as "good effect" in Table II are 30 responses, 27 of which were obtained when the titration was increased. Temporary or no effect was obtained in 12 menstrual periods, of which 6 were associated with increased protamine titrations. The response to oral toluidine blue was not impressive but the number of patients so treated was too small to evaluate.

The response of many of the patients with menorrhagia to a single intramuscular injection of protamine is difficult to explain, in that the duration of intramuscular protamine action is probably less than 4 hours (4). Most

SURGERY, GYNECOLOGY AND OBSTETRICS

patients who reported a reversion from profuse to normal flow remained normal for the rest of the menstrual period. These results were obtained when protamine was given intramuscularly on the second or third day of flow. This generally was coincident with an increase in the protamine titration and the onset of profuse bleeding. Temporary or poor results occurred most frequently when protamine was given on the first day of menstruation, even though in some patients the titration was increased at this time.

The mechanisms involved in menstruation and menorrhagia are not well understood and the nature of the systemic change responsible for the protamine titratable abnormality in the blood of these patients is even more obscure. Hence, these data cannot be interpreted with reference to the physiology of menstruation or coagulation. The fact that many of these patients appeared to respond to protamine sulfate is not in itself sufficient to conclude that the systemic blood disturbance in menorrhagia is the same as that produced by the injection of commercial beef heparin. Therapeutic measures in menstrual disorders often can only be evaluated in terms of subjective descriptions by the patient. The difficulty in evaluation is further complicated by the fact that not all menstrual periods in women with menorrhagia are abnormal. Hence, a much larger series of normal women and patients with menorrhagia, studied with reference to their protamine titrations and response to intramuscular protamine injections

and oral toluidine blue, will estimate the therapeutic possibilities of these agents accurately.

SUMMARY

- 1 The presence of protamine abnormality was observed at the menstruation. This abnormality was commonly and more extensively in women with menorrhagia than in those whose menstrual periods were normal.
- 2 Many patients also had a prolonged blood clotting time and a mild to moderate thrombocytopenia. Prothrombin and fibrinolysin was observed in only 1 patient.
- 3 The blood studies and clinical course following the administration of protamine sulfate or toluidine blue in a group of 34 women with menorrhagia are presented.

MULTIPLE PRIMARY CANCER

A Study of Thirty-six Patients

W D BARRETT, M D, K T MILLER, M D, and C R FESSENMEYER, M D,
Detroit, Michigan

IN spite of the fact that tremendous advances have been made in the fields of cancer research and the related sciences since Billroth first reported the occurrence of multiple primary malignant neoplastic disease nearly 80 years ago, the true biological significance of this condition remains obscure. Final clarification depends primarily on the correct explanation and evaluation of the various extrinsic and intrinsic factors that initiate and control malignant anaplastic cytological changes and secondarily on the statistical contributions of clinical medicine. Ewing has stated that "the study of the conditions under which cancer develops belongs to clinical medicine and pathology, while the investigation of the cell processes calls upon all of the fundamental medical sciences." With this in mind, and prompted by the fact that an increasing number of cancer patients seen in the Department of Surgery at Harper Hospital were observed to have been afflicted with a second primary malignant lesion, we made the following résumé of current thought on the subject with a report of 36 cases.

MODE OF ORIGIN

As reliable scientific data have accumulated, the theory of unicentric origin, which holds that neoplastic processes develop exclusively from a single cytologic focus, has gradually given way to the theory of multicentric origin. The latter proposes that neoplastic transition may occur independently at two or more isolated points, either simultaneously or at variable intervals, thus producing independent multiple lesions or solitary lesions by the coalescence of adjacent foci.

In an excellent review of the subject, Slaughter discusses the following evidence favoring

the multicentric origin of both benign and malignant tumors. Examples of the former include pigmented nevi, keratotic warts, lipomas, neurofibromas (von Recklinghausen's disease), papillomas of the urinary bladder, multiple polyps of the stomach and colon, and fibromyomas of the uterus. Examples of malignant neoplastic disease of diffuse origin include the leucemias, Hodgkin's disease, and idiopathic multiple hemorrhagic sarcoma (Kaposi's disease). Multiple myeloma has also been cited as an example, but the mode of origin of this disease is subject to question. Brill Symmer's disease (giant follicular lymphadenoma) is regarded by some investigators as a precursor of lymphosarcoma.

Microscopic evidence of the multicentric origin of malignant neoplastic disease is commonly found in lesions such as intraepithelial epidermoid "carcinoma in situ" (Bowen's disease) and in the malignant degeneration of widely separated polyps of the colon. "Carcinoma in situ" has been demonstrated in skin, cervix, larynx, and other organs by Broders (28), in the breasts by Foote and Stewart (28), and by Mallory (28) in the gastric mucosa. Ewing has stated that "precancerous" or pre-invasive anaplastic cytological changes can be demonstrated in areas outside of the limits of the frankly invading carcinoma.

Although this evidence does not conclusively prove the multicentric origin of multiple neoplastic disease, or exclude the possibility of unicentric origin, it offers tangible evidence that isolated anaplastic cellular changes do occur.

INCIDENCE

The incidence of carcinoma based on post-mortem findings at Wisconsin General Hospital (University of Wisconsin) (7), University Hospital (University of Michigan) (7), and

United States Average (32)	6.8
Combined European and United States Average (32)	3.90
	1.84

the Mayo Clinic (7) averages about 30 per cent of autopsies. Warren and Gates (32) report an incidence of 13.8 per cent based on a review of 115,813 postmortem examinations. The incidence of multiple primary malignant neoplasms has been variously reported between 0.3 and 6.8 per cent of all cancer cases as shown in Table I.

AGE AND SEX

The average age of occurrence of multiple primary malignant tumors varies, according to the literature, between 50.4 and 62.1 years. Insufficient data have accumulated to distinguish any significant correlation between age and multiplicity of lesions. Available statistics regarding the incidence in the two sexes are inconclusive, however, they seem to indicate a slightly higher incidence in males.

SUSCEPTIBILITY, IMMUNITY, AND
HEREDITY FACTORS

Computations by Bugher based on cancer statistics of the United States during the period 1920 to 1928 indicated that the actual incidence of multiple primary neoplastic disease is greater than can be expected on the basis of chance alone. The preponderance of opinion seems to favor a tumor diathesis or susceptibility factor in a certain percentage of the population, however, Ewing, Hanlon, and Seecof (16) have suggested that the incidence is compatible with the accidental rate. Ewing states that "the validity of assuming the existence of

a predisposition to cancer based on current available statistics is subject to doubt. So many events of widely separated significance have been included in the reports of multiple malignancies that no definite conclusions can be drawn. Multiple malignancy is an accidental coincidence of the biological factors in the incidence of tumors. Clinical studies indicate that there is, among human beings, a general susceptibility to tumors, but as a rule, the susceptibility is negligible and the disease is not developed until the real affective causes of the disease are brought into play." In the statistics available, approximately 26 to 29 per cent of patients with multiple primary malignant tumors have a family history of cancer. Until further evidence has accumulated, no definite conclusions can be drawn concerning the significance of the immunity, susceptibility, or heredity factors.

COMBINATIONS

The potential combinations of primary malignant tumors are numerous, but Slaughter has shown in his analysis of 1,868 cases that there is a striking tendency for them to occur in the same organ or in paired organs (54.3 per cent). This observation has also been made by Lichtman and Stalker, Phillips, and Pemberton. Ewing reported that bilateral primary carcinoma of the breasts occurs in 1.5 per cent of the cases. According to the literature, multiple primary neoplasms occur most frequently in the skin or in combinations with the skin. This group constitutes more than 50 per cent of the cases in many of the earlier reports. As Slaughter points out, the fact that the skin is the system most frequently involved is not surprising, when one considers the relative size of this organ and the frequency with which it is exposed to external chemical and physical carcinogenic stimuli. Schreiner and Wehr observed that basal cell carcinoma is found more frequently than squamous cell carcinoma in multiple primary tumors involving the skin. The next most commonly involved system is the gastrointestinal tract, followed by the genitourinary system. According to Slaughter's work, the order of frequency of involve-

ment of the several divisions of the gastrointestinal tract is colon, first, combinations of colon and stomach, second, and stomach, third, which, as he points out, is somewhat of a surprise as gastric carcinoma is not generally thought of as being multiple

As would be expected, the highest incidence in the paired organs occurs in the breasts, ovaries, testicles, and kidneys in that order

Multiple primary tumors involving two different systems occur most frequently in the gastrointestinal and genitourinary systems. Second in frequency are tumors involving the breasts and genitourinary tract

Multiple sarcomas are relatively rare, however, combinations of carcinoma and sarcoma are not infrequent

Certain combinations, particularly those involving the same tissue or same organ, are frequently difficult to prove because of the problem of excluding metastasis. Examples of these are multiple primary lesions confined to the ovaries, breasts, skin, colon, and combinations involving the ovaries and gastrointestinal tract (Kruckenberg). Teratomas also give rise to doubt in certain cases

THE SIGNIFICANCE OF THE ENDOCRINE SYSTEM IN MULTIPLE PRIMARY NEOPLASMS OF PAIRED ORGANS

The existence of a relationship between the estrogenic hormones and carcinoma of the breast is generally accepted, however, the exact significance of this relationship is not clearly understood. It is well known that surgical castration following primary carcinoma of the breast frequently alters the course of the disease in patients in the premenopausal state

Dockerty (4) states that granulosa cell and theca cell tumors occasionally produce adenocarcinoma of the breast and uterus as the result of a hormonal disturbance

Slaughter has suggested that if carcinoma of the breast is a systemic disease predicated on an endocrine background, then the bilateral occurrence of breast cancer could be readily explained. Likewise, bilateral carcinoma of the ovaries and testicles could be explained on a similar basis rather than on the basis of chance alone

CRITERIA FOR DIFFERENTIATING PRIMARY MALIGNANT NEOPLASTIC DISEASE

Billroth (32) proposed the following criteria which have generally been discarded because they were too strict: (1) the tumors must have a different histological appearance, (2) they must arise in different locations, and (3) they must each produce their own metastasis. The third postulate would obviously rule out many cases which are beyond reasonable doubt

Goetze (15) revised Billroth's criteria slightly and proposed that (1) each tumor must present the microscopic and macroscopic picture of the usual tumors involved, (2) the possibility of metastasis must be excluded with certainty, and (3) diagnosis must be confirmed by the character of the individual metastasis. As in Billroth's criteria, the third postulate falsely eliminates many true malignant primary neoplasms

Dissatisfied with these, Warren and Gates (32) liberalized their criteria as follows: (1) each tumor must present a definite picture of malignancy, (2) each tumor must be distinct, and (3) the probability of one tumor being a metastasis of the other must be excluded

Many reported cases have been disregarded in the statistical reviews in the literature because they did not conform to the criteria of the author concerned. Many others occurring in the same or paired organ or in the same or adjacent systems have been subject to question

DISCUSSION OF STATISTICAL DATA

Early in the course of this investigation it was realized that the number of cases acceptable for this report would not be as large as expected because of the difficulty in proving that the second neoplasm concerned was an independent primary tumor rather than an extension of the original growth

More than 60 per cent of the cases originally reviewed were discarded for one reason or another. The chief cause for elimination was due to the fact that clinical diagnosis of one or the other of the tumors had not been conclusively confirmed by histopathologic proof. Other cases were discarded when it was revealed by their histories that the original primary lesion had been diagnosed and treated

SURGERY, GYNECOLOGY AND OBSTETRICS

TABLE II —PATIENTS WITH FAMILY HISTORY OF CANCER

Case No	Case diagnosis	Family history
19	Carcinoma of breast and ovary	Mother died carcinoma of stomach
22	Carcinoma of breast and cervix	Mother died carcinoma of stomach
11	Carcinoma of sigmoid colon	Mother died carcinoma of unknown site
9	Carcinoma of breast and stomach	Mother has carcinoma of breast
5	Carcinoma of rectum and colon	Father died carcinoma of bladder
32	Sarcoma of nose and carcinoma of breast	Mother had carcinoma of uterus Grandfather died carcinoma of stomach Two aunts died carcinoma of unknown site
25	Carcinoma of breast and uterus	Father died carcinoma of prostate Brother died carcinoma of bowel Four sisters died carcinoma of breast
27	Carcinoma of breast and uterus	Brother died carcinoma of lip Brother died carcinoma of liver

TABLE III —MULTIPLE NEOPLASMS OF THE GASTROINTESTINAL TRACT

Case No	Age years	Sex	Diagnosis	Interval	Diagnosis
4	47	F	Adenocarcinoma of sigmoid colon	4 yr 7 mo	Adenocarcinoma of transverse colon
5	50	M	Adenocarcinoma of rectum	8 yr 6 mo	Adenocarcinoma of transverse colon
6	40	F	Adenocarcinoma of transverse colon	6 yr 9 mo	Adenocarcinoma of sigmoid colon
7	50	F	Adenocarcinoma of cecum	10 yr	Adenocarcinoma of sigmoid colon

The age at the time of diagnosis of the first primary lesion varied from 28 to 78 years, and averaged 52.0 years. The age at the time of onset of symptoms of the second primary also varied between 28 and 78 years, and averaged 54.9 years. The interval between the onset of symptoms and the time of diagnosis of each neoplasm was so short in the majority of cases that this factor was considered negligible in computing the time intervals between lesions. The interval between the time of diagnosis of the first primary and the onset of symptoms of the second primary lesion ranged from 0 to 14 years, and averaged 3.22 years.

A reliable family history was obtained in 30 of the 36 cases, and of this number, 8, or 26 per cent, had a positive history of malignant disease, as noted in Table II.

It is of interest to note that in Case 25 there was a high incidence of carcinoma of the breast in the family. In this small series, however, it is impossible to draw any conclusions regarding a familial susceptibility factor.

The cases herein reported have been grouped according to the systems and system combinations concerned. In the 4 cases in which the gastrointestinal system alone was involved, the tumors were confined to the colon and rectum and there was no evidence of multiple polyposis in any case (Table III). Several cases of synchronous multiple lesions of the large bowel were reviewed, but were discarded on the basis that metastasis could not be ruled out. The interval between the occurrence of the two lesions in this series is worthy of note, the average being 7 years and 4 months. Malignant lesions of the upper gastrointestinal

at some other institution. Still others were discarded because the lesions concerned were confined to paired organs (as the breasts, ovaries, and kidneys) and the possibility of metastasis could not be ruled out. In spite of the fact that a large percentage of the cases reviewed did not fulfill the requirements of the criteria used, it was felt that many of them represented true cases of multiple malignant primary tumors.

We have included in this report only those cases (1) which have been proved to be malignant tumors microscopically, (2) which presented the gross and microscopic characteristics of the usual primary neoplasms found in the organs involved, and (3) in which the possibility of the second tumor being a metastatic lesion has been excluded to our satisfaction.

Thirty-six cases were finally selected from the Harper Hospital records of the last 20 years. In this group, there were 71 primary lesions, including 63 carcinomas, 5 sarcomas, 2 malignant teratomas, 1 malignant endothelioma, and 2 cases of myelogenous leukemia. Thirty-two of the patients were female and 4 were male, which represents a higher proportional incidence in women than previously noted in the literature.

TABLE IV—MULTIPLE NEOPLASMS OF THE GENITOURINARY TRACT

Case No	Age years	Sex	Diagnosis	Interval	Diagnosis
1	51	F	Sarcoma of ovary	3 yr 9 mo	Adenocarcinoma of uterine fundus
2	49	F	Sarcoma of ovary	2 yr 11 mo	Squamous carcinoma of uterine cervix
3	52	F	Adenocarcinoma of ovary	8 mo	Squamous carcinoma of uterine cervix

tract, which have frequently been reported in the literature, are conspicuously absent in this series. In only 1 of the cases reported was there a family history of cancer.

Three of the patients were found to have multiple neoplasms confined to the genitourinary system, as shown in Table IV. It is of interest to note that all of these are combinations of ovarian and uterine tumors in which the ovary became involved first. As previously indicated, this group may not represent the correct percentage involvement of this system because of the fact that multiple primary lesions confined to the ovaries were disregarded. None of these patients had a positive family history of malignant neoplastic disease.

The 6 cases of multiple primary neoplasms involving the breasts and gastrointestinal tract, shown in Table V, are of considerable interest. Fifty per cent, or 3 cases, are combinations of the rectosigmoid colon and ovaries in which the initial lesion occurred in the bowel. The possibility of Kruckenberg tumors and direct extensions of the initial lesion were ruled out to our satisfaction in these 3 cases, however, it is realized that they may be a subject of controversy. Several cases with similar combinations were discarded because these possibilities could not be reasonably excluded.

As previously noted in Table III, the time interval between the initial and subsequent primary lesions confined to the large bowel averaged 7 years and 4 months. In contrast to this, it is of interest to note that when the second primary lesion involved the ovary, the time interval was reduced to 7 months. Accordingly, the survival rates were markedly reduced.

TABLE V—MULTIPLE NEOPLASMS OF THE GASTROINTESTINAL AND GENITOURINARY SYSTEMS

Case No	Age years	Sex	Diagnosis	Interval	Diagnosis
11	44	F	Adenocarcinoma of rectosigmoid	2 mo	Adenocarcinoma of ovary
12	56	F	Adenocarcinoma of uterine fundus	7 yr 2 mo	Adenocarcinoma of cecum
13	59	F	Hypernephroma of kidney	5 mo	Adenocarcinoma of sigmoid colon
14	28	F	Adenocarcinoma of rectum	1 mo	Adenocarcinoma of ovary
15	41	F	Adenocarcinoma of uterine fundus	14 yr	Adenocarcinoma of colon
16	59	F	Adenocarcinoma of sigmoid colon	1 yr 6 mo	Papillary carcinoma of ovary

In our experience, this combination seems to have a much poorer prognosis for survival than other combinations. As previously noted, this observation seems clinically significant, regardless of whether the ovarian neoplasms are primary or metastatic, in that it raises the question of the advisability of castrating all female patients with carcinoma of the gastrointestinal tract at the time of initial resection.

For example, in Case 14, a 28 year old white female was found to have grossly normal ovaries at the time of operation for a fairly early carcinoma of the rectum (Miles operation). Because of the patient's age and desire to have another child, and the lack of evidence of metastasis or local extension of the neoplasm, the ovaries were not removed. Approximately 2 months later, this patient returned with a rapidly enlarging abdominal tumor which proved to be a papillary cystadenocarcinoma of the ovary. Eighteen months later the patient expired as the result of a generalized abdominal carcinomatosis. It seems reasonable to assume that her life would have been extended if the ovaries had been removed at the initial operation.

Eleven, or 30 per cent, of the cases included in this report were combinations of breast and reproductive organs, as indicated in Table VI. The average time interval between lesions in this group was 17 years. The ovaries were involved in 3 cases and the uterus (cervix) in

10	78	F	Scurrhous carcinoma of breast	None	Adenocarcinoma of rectum

in contrast to the early statistical reviews which reported an incidence of more than 50 per cent

In Case 36 the patient had three primary neoplasms. The first was an adenocarcinoma of the jejunum, followed 8 years later by a carcinoma of the kidney and a squamous cell carcinoma of the larynx. This patient is also reported to have a carcinoma of the bladder and a carcinoma of the prostate, but histopathologic evidence had not been obtained at this writing.

The time interval between lesions in this group, for the most part, was relatively short.

DISCUSSION

The contributions of clinical medicine to this subject have been limited for several reasons. Foremost is the failure of the medical profession as a whole to report all significant clinical observations and statistical data. Conclusions regarding the incidence of cancer must be based on the relatively small percentage of cases that are reported in the scientific literature and the vital statistics surveys of the few countries publishing reliable reports. The number of cases of primary and multiple malignant disease that remain undiagnosed and unreported is highly speculative. Probably a large majority of these cases are never seen by the medical profession, particularly those in the less civilized parts of the world. Many others no doubt die of accident or intercurrent disease before the second primary malignant tumor manifests itself clinically. Still other cases are undiagnosed at autopsy because of the impracticability of serially sectioning all tissues.

Other limitations to the accuracy of statistics include the diversity of opinion re-

the remaining 8. Two of the tumors involving the ovaries were teratomas.

Of this group, adequate histories were available in only 10 cases which revealed that 6 of the patients had passed the menopause at an average age of 50 years and the remaining 4 were between the ages of 44 and 47 years. Eighty per cent of this group were parous. Menstrual histories were essentially normal in all cases but 1.

In this small group, there is nothing to indicate endocrine imbalance, and the group as a whole falls well within the limits of normal with regard to menstrual history and fertility.

Table VII includes 3 cases in which one of the primary lesions occurred in the breast and the other in the gastrointestinal tract. Noteworthy only is the fact that all of the breast lesions were of the scirrhus variety.

The final category of multiple neoplasms is composed of miscellaneous combinations of lesions involving unrelated organs and systems. Table VIII indicates the nature and locations of these lesions.

Neoplasms involving the skin constitute only 8.3 per cent of this total series, which is

garding the classification of malignant tumors in general and the absence of a set of criteria that will differentiate true multiple primary neoplastic disease from extension or metastasis beyond any question of doubt. Until such criteria have been proposed, tumors having similar histopathologic patterns or occurring in the same system or paired organs will always be subjects of controversy.

The incidence of multiple primary malignant neoplastic disease based on the law of chance has been variously estimated in the neighborhood of 3 per cent. The consensus of opinion seems to favor the theory that the actual incidence is greater than can be accounted for on the basis of chance alone. If this is correct, it seems reasonable to assume that this condition is either an inevitable sequence in the course of uninterrupted neoplastic genesis or that susceptibility, resistance, and heredity factors exist.

The apparent and actual incidence of multiple primary malignant tumors should gradually rise further above the incidence expected on the basis of chance alone because of the following reasons:

- 1 Progressive improvement in methods for accumulating accurate cancer statistics from all sources should bring more cases to light.
- 2 Progressive education of the laity, as well as the medical profession, should increase vigilance for the disease and result in earlier diagnosis and treatment.
- 3 Progressive increase in the number of individuals living in the "cancer age" group should result in an increase in the incidence of multiple primary cancer as well as of initial cases.
- 4 Progressive increase in the cure and survival rates resulting from improved methods of cancer detection and cancer therapy should permit the occurrence of additional primary tumors in the same individual.

As the actual incidence of cases increases, the clinical significance of multiple primary neoplasms becomes increasingly important from several standpoints. First, the importance of a thorough periodic examination of all cancer patients for the development of subsequent primary lesions as well as metastasis cannot be overemphasized. Secondly, in view

of our present knowledge of multiple primary neoplasms and the frequent involvement of the ovaries by a second primary or metastatic lesion following carcinoma of the uterus or gastrointestinal tract, the surgeon must always consider the advisability of castration at the time of surgery for the initial cancer. Furthermore, the problem of castration of premenopausal women with primary carcinoma of the breast, as a method of controlling the development of subsequent primary lesions as well as metastatic lesions, is worthy of consideration.

SUMMARY

A survey of 36 cases of multiple primary malignant neoplasms, based on records obtained from the Department of Surgery at Harper Hospital, revealed an average age in incidence of 52.0 years for the appearance of the initial primary tumor, and an average time interval between primary tumors of 3.22 years. There were 32 females and 4 males in this series, a ratio of 8 to 1.

Calculation of the incidence rate in systems and organs reveals that 17 patients, or 47 per cent, had a primary lesion in the gastrointestinal tract, 15 patients, or 41 per cent, had involvement of a breast, and 9 patients, or 25 per cent, had a primary lesion in one ovary.

SURGERY, GYNECOLOGY AND OBSTETRICS

The time interval between lesions was greatest in those confined to the gastrointestinal system, and shortest in those involving the ovaries and gastrointestinal system. In this series, there was a family history of cancer in 26 per cent of the cases in which reliable histories were available.

FRACTURES ABOUT THE ELBOW IN CHILDREN

FRACTURES involving or adjacent to the elbow joint are important, they occur frequently, and excellent functional results are often difficult to obtain. Accurate reduction is required to restore the carrying angle, flexion, extension, pronation, and supination.

Supracondylar fractures are the most common about the elbow. Volkmann's contracture follows supracondylar fracture more often than any other injury. The anatomy about the elbow joint contributes to impairment in circulation. The distal fragment is usually displaced posteriorly, stretching the terminal portion of the brachial artery over the brachial fragment. At the elbow the brachial artery passes through a closed space bounded posteriorly by the humerus, and laterally and medially by the intermuscular septa which are continuous with the deep fascia that forms the anterior boundary. The occurrence of edema in this space may impair the circulation.

Considering these anatomical facts, circulatory impairment following supracondylar fracture is relatively rare. When it does occur, every effort must be made to restore adequate circulation by correction of the gross displacement of the fracture, elevation, parasymphetic block and, in rare cases, surgery. There are few more distressing conditions seen in the practice of orthopedic surgery than a severe Volkmann's ischemic paralysis.

Nerve lesions are rare, when they do occur the radial nerve is the most often involved, the median second, the ulnar almost never. The radial nerve is subject to injury as it passes over the anterior margin of the proximal fragment in the interval between the brachialis and brachioradialis muscles. Usually the radial nerve paralysis is temporary. The roentgenograms should be studied to differentiate between supracondylar fracture, condylar fracture, and posterior dislocation of the elbow.

Reduction should be accomplished as soon as possible. General anesthesia is used. Traction is placed on the forearm with the elbow extended and any medial or lateral displacement of the distal fragment corrected by manipulation. While moderate traction is continued, the distal fragment is pushed forward, the proximal fragment backward, and the elbow flexed so that the palm of the hand points toward the sternoclavicular joint. This position places the forearm medial to the arm when the elbow is flexed, therefore, when the elbow is extended the carrying angle will be preserved. The forearm should not be flexed above 45 degrees. If the radial pulse is not palpable at this point, the elbow should be extended sufficiently to allow palpation of

SURGERY, GYNECOLOGY AND OBSTETRICS

pulse The forearm is held in this position by adhesive strapping When this method is used the circulation must be watched with great care following the manipulation At the end of 3 or 4 weeks sufficient callus is usually present to allow removal of the adhesive The child is encouraged to increase the motion in the elbow by active use Passive motion should not be used Forceful manipulation or passive stretching of the elbow to produce extension, either by physiotherapist or the relatives is to be condemned as is also the carrying of bricks, books, etc Active use of the elbow and active use alone should be employed to increase the motion in the joint

Condylar fractures It is important to differentiate between supracondylar and condylar fractures The former can be treated by conservative means in nearly all instances while the latter require early open reduction and adequate internal fixation to insure satisfactory reduction and to prevent disturbances in growth and arthritic changes Due to the presence of the carrying angle, fractures of the lateral condyle are much more common than fractures of the medial condyle Fracture or epiphyseal separation of the medial epicondyle is more common than fracture of the medial condyle but not as common as fracture of the lateral condyle

In either fracture of the medial or lateral condyle, separation and rotation of the fragment is usually seen The lateral condyle is displaced and rotated by the pull of the extensor muscles, the medial by the flexor muscles In the roentgenograms the fragments always appear smaller than they actually are as complete ossification of the condyle has not occurred The condylar fragment is small and difficult to manipulate, as it is practically impossible to grasp and replace it accurately Even if one is successful in securing an accurate reduction, the pull of the muscles will

distract the fragment despite any form of external fixation

When these fractures are treated by manipulation nonunion occurs As the fracture line passes through the growth centers of the lower end of the humerus, disturbance in growth will occur If the lateral condyle is fractured, as the child grows the medial side of the humerus will grow faster than the lateral, thus creating a gradually increasing cubitus valgus deformity If the medial condyle is fractured the lateral portion of the lower end of the humerus will grow faster than the medial side and there will be gradual decrease of the carrying angle with the development of a gunstock deformity Irregularity of the lower end of the humerus causes a posttraumatic arthrosis of the elbow With nonunion of the lateral condyle and increase in the carrying angle, delayed ulnar palsy may be seen during adult life

To prevent these complications, early operation and internal fixation should be employed The condylar fragment should be rotated into its anatomic position In many instances the major portion of the fracture line is covered with cartilage and only a small central area of bone is noted in both fragments Cartilage heals poorly, consequently, to obtain union it is necessary to oppose the osseous tissue Internal fixation is imperative to maintain the position of the fragments, without it separation will occur as a result of the muscle pull The fragment can best be held by means of a small rustless steel nail If there is a tendency for the condyle to rotate, a second nail may be necessary The end of the nail should be palpable beneath the skin At the end of 6 weeks, usually under local anesthesia, the nail is removed

This method has the theoretical disadvantage of passing a foreign body across the epiphyseal line We have not noted blocking of

EDITORIAL

the epiphysis or impairment of growth as a result of the nail

Posterior dislocation of the elbow in children is often associated with fracture or epiphyseal separation of the medial epicondyle. At the time when the dislocation is reduced the medial epicondyle may be caught in the joint.

The above accounts for 90 per cent of the fractures about the elbow in children (supracondylar 65 per cent, condylar 25 per cent, in our series). Fracture of the neck of the radius, fracture of the ulna with dislocation

of the head of the radius, fracture of the olecranon and T condylar fractures accounted for the remaining 10 per cent. These are usually treated by methods similar to those employed in adults, except that in fracture of the neck or head of the radius, the head of the radius should not be removed in a growing child as cubitus valgus will result. Also fractures of the ulna with dislocation of the head of the radius can often be treated conservatively in a child while these fractures usually require operative therapy in an adult.

JOHN PAUL JONES
1734-1792

Don't Give Up the Ship - The USS Bonhomme Richard

THE SURGEON'S LIBRARY

THE BOOK SHELF

DEATH COMES FOR THE ADMIRAL

ESTHER H VINCENT, Evanston, Illinois

JOHN PAUL JONES started life in a wee cottage in Galloway, in that same western Scotland that nourished Wallace and Bruce, Bonnie Prince Charlie, and Bobbie Burns. His parents, John Paul and Jean Macduff, Low and High Scotch, respectively, handed down to their little son the poetic romanticism of the Lowlanders and the physical vigor and "derring-do" of the Highlanders. John Paul, Senior, had come from Fife, where his father was a gardener-innkeeper, and had taken service as a landscape architect on the estate of William Craik, Laird of Kirkcudbright. Craik was the natural son of the eminent surgeon, James Craik, and had achieved a favorable reputation throughout Britain as an inventive agriculturalist.

In their cottage on a granite headland of the Solway Firth, John and Jean Paul produced seven children, four boys and three girls. The two youngest boys, however, died in infancy, and the eldest girl died before she was twenty. The eldest son, William, was adopted by a Virginia planter, William Jones, who took a liking to the lad, while on a visit to his home-folks in Scotland. That left to the family John Paul, Junior, and the two little girls, Mary and Janet.

The future founder of the United States Navy was born on the sixth of July, 1747, the year after the famous battle of Culloden, while the strains of "Scots wha hae with Wallace bled" still echoed over the heather. Efforts have been made to assign him to other than his gardener father—to the Earl of Selkirk on St Mary's Isle, to Mr Craik, and to Uncle George Paul. But the probability is that he was quite unromantically legitimate.

His scanty childhood included a meager education at the parish school, and an extensive education at the seashore. His toy frigates had

given way to fishing yawls, and his boy companions to bronzed sailors before he was twelve. At that age he was apprenticed to a ship owner, and made his first voyage to the new world. While still in Virginia, he had his indentures returned to him, his ship-owning firm having changed hands, and he went back to Scotland on a British man-of-war. Then as third mate on a "slaver," he plowed the steaming waves to Africa, and at the age of nineteen, found himself chief mate on a Jamaica-Guinea brigantine. In this nefarious trade, sailors died almost as fast as their human cargo, and epidemics were frequent. Young John wrote home about his "several very severe fevers," and at length gave up his job. Stranded in Jamaica, he joined a troupe of actors and toured the West Indies, thus developing his native histrionic ability and achieving skill in speech and stage presence.

Tired of island-jumping, he sailed on a ship bound for Britain. Early in the voyage, both the captain and the first mate died of fever, this sort of thing being quite characteristic of tropical malaria before the days of quinine and mosquito crusades. John Paul took command, and, on arrival in port, was made master at the age of twenty-one. By this time, his father was dead, and, after arranging family affairs, John again went down to the sea in ships.

Now occurred the unfortunate Mungo Maxwell incident. Maxwell, a fellow Scotsman, was ship's carpenter on a voyage to Tobago. So shiftless and lazy was he, that Captain Paul thought to cure him with the cat-o'-nine-tails. Maxwell seemed none the worse for his whipping, but, when, some time later, he died on another ship, John Paul was accused of his murder. The evidence proved that Maxwell's death was due solely to fever, but the affair put the young captain in a very miserable as well as a precarious situation.

SURGERY, GYNECOLOGY AND OBSTETRICS

His difficulties were not lessened by his own attacks of malarial fever, and by the strain on his constitution occasioned by the summer heat of the tropics. In Tobago, his "isle of misfortune," there later took place another affair of serious import. During a mutiny at sea a rebellious sailor impaled himself on Captain Paul's sword. The twenty-six year old commander was so upset over his two unfortunate experiences with violence, that he disappeared from history for two years. Speculation has suggested that he took refuge in piracy, but there is no worthy evidence as to this, and knowledge of his character contradicts it.

In 1774, John Paul turned up again in Fredericksburg, Virginia, and there found brother William mortally ill. After the funeral, John took over the administration of William's estate, and showed some signs of wanting to become a planter, himself. His glamor-boy personality won for him a rather dazzling social success, and the presence in the neighborhood of a certain Dorothea Dandridge (afterward married to Patrick Henry) was an added incentive to permanent retirement from the sea. But the American Revolution was brewing, and John Paul, who had now added Jones to his name, walked with brisk step from the pillared porches of Virginia to the quarter-deck of a fighting ship.

John Paul Jones was the sort of man who always commands attention. His keen, wild look, heritage of his Highland mother, augmented his charm. Of medium height, he was slender, admirably proportioned, and with classical features. His hair and eyebrows were black, his eyes brilliantly dark. He had a military grace of motion and a remarkable facility of movement. His sweet Scotch baritone fell most agreeably on the ear, and his power of conversation was extraordinary. His dress was invariably good, his personal habits pleasant. His life as a sea captain had produced a certain air of withdrawal, of seeming arrogance, which put lesser men in their places. Since many of these "lesser men" did not like to be put in their places, Paul Jones acquired a good many enemies, some of them in the seats of the mighty.

He reached Philadelphia at the bidding of the Congressional Marine Committee in 1775, and was placed in a group of experienced persons to consider how to make a navy. Now began his life of vexatious delays and bitter disappointments for which all his naval victories and all the adulation of two continents could hardly compensate. Personal jealousies and petty minds continually got in his way. Along with him in

the budding United States Navy were "political skippers," soon to be dismissed or to fall into harmless byways. But Jones was the first to hoist the Stars and Stripes as the ensign of the Republic, and was named by Congress to command the *Alfred*, crack frigate of the weak, little American line.

Burgoyne's surrender to Gates at Saratoga was the turning point of the Revolution, and it was Jones who was chosen to carry the news to France in the *Ranger*, the first Yankee frigate to cross the Atlantic. His arrival brought him a new friend in the canny Benjamin Franklin, then Minister to France. It also brought a new friend to the United States, for France now left the harbor of neutrality for the seas of intervention. Jones' association with French admirals, statesmen, nobles and plain citizens added to his own reputation and to that of his country. A series of daring raids on the coast of England, including an incursion to burn the shipping at Whitehaven (across the Solway from his birthplace), gave Britain a frightening experience. In April 1778, the *Ranger* captured the *Drake*, presenting the very new United States with its first victory over a ship of war. But the *Ranger's* commander had the very devil of a time with French and American red-tapism, bungling officials of both nations, treacherous and jealous subordinates, and had the utmost difficulty getting his prize money and meeting his crew pay rolls. All this produced a terrific mental strain on the struggling commander.

But there were interludes of glory and romance in Paris. Flirtatious letters from aristocratic French ladies give proof that one should not write love letters to famous men who keep an orderly correspondence file. Jones received a sword of gold and a medal of merit from Louis XVI, and a purse of 50,000 dollars from Louis and good friend, Adelaide de Bourbon, Duchess of Chartres. Given command of an old tub of an East Indiaman, *Le Duras*, he changed its name to *Le Bonhomme Richard* in honor of Franklin's "Poor Richard," and set out with three other vessels on the adventure that ended with moon-lit victory over the English *Serapis*, and made famous the phrase, "I have not yet begun to fight."

Paris celebrated the conquest with wild delight. The King made Jones a Chevalier, and the Duchess of Chartres greeted him with royal triumph as he laid the English Captain's sword at her feet. News of treachery and conspiracy at home led Jones to return, a "wrathful Achilles of the sea." Congress was suffering from its usu-

VINCENT DEATH COMES FOR THE ADMIRAL

al reaction to excessive hero worship, but the notous passage of the *Alliance* under command of the psychopathic Landais did much to vindicate Jones' honor. Nevertheless, the Scotch-American hero continued to experience disappointment and frustration. Sailing to the Caribbean in vain expectation of a meeting with Spanish and French admirals, Jones had to cope with a long summer of tropical heat and bad food. Already sick with thwarted hopes, he fell easy prey to the marsh fevers of Porto Cabello. Relief came only with autumn and cold water therapy. However, intermittent fever plagued him all his days.

On his return to the States at War's end, he sought recuperation at Pennsylvania's Bethlehem, a favorite health resort for army and navy officers. His name still may be seen in the archives of the hospital kept by the Moravian Brethren. He was only thirty-six years old, but was like a tired and sick old man. Owing to financial reticence on the part of both the United States and France, Paul Jones had to rely on his interest in the whale-oil trade for economic security. But he continued to serve his country generously in spite of inadequate gratitude.

Sent abroad as a special envoy to adjudicate and collect delicate international claims, he proceeded to Paris. Here he had personal interests, also, in connection with the ladies. The most serious love affair of his life was conducted on the fringe of the royal court with a mysterious Mme T——, said to have been a natural daughter of Louis XV, an apparently very lovable woman, who disappeared in the mists of the Reign of Terror. Jones went on to Copenhagen to play his part in the tragicomedy of the Danish indemnity affair. Landais had holed up American ships in Bergen, then a Danish port, and Denmark had handed them over to Britain. The journey north was accompanied by great physical exposure, and on arrival Jones was forced to spend several days in bed. Hitherto blessed with a Napoleonic imperviousness to small ills, he had finally reached the point where he "couldn't take it."

Paul Jones was now ranking officer in the non-existent American navy, but, being unemployed for the time, he was open to offers from foreign countries. Catherine of Russia had heard of the handsome naval hero and requested his services. Jones accepted, with French minister Jefferson's blessing, and set out for Unholy Russia. Since direct passage was prevented by ice, Jones made a dangerous detour to Estonia in a small, open boat, manned by a few frightened Swedish sailors.

Badly battered, he landed at Revel after several days and nights of constant struggle with cold, wind, waves, and ice. He reached St. Petersburg in April of 1788, and promptly went to bed with a pulmonary upset. This exposure, added to that already suffered on the journey to Denmark, was a deep shock to his already weakened constitution. Exposure to the wily Catherine and to her treacherous Prince Marshall, Potemkin, was a further shock to the trusting Caledonian.

After a period of flattery and adulation at Court, Jones made the thousand mile journey across the bleak Russian steppes to the pretentious but disease-ridden military post of St. Elizabeth. Both Catherine and Potemkin were potentially dangerous to their new naval advisor, but it was to the interest of both of them that he be given a chance to make use of his talents. His was an uncanny knack of being able to succeed with poor material in both men and ships. And his "I have not yet begun to fight" spirit served him well. Though tired and half-sick, and caught in a net of intrigue, the doughty Russian Vice-Admiral won an astonishing victory over the Turks on the Black Sea. That the inept Prince of Nassau won the glory was characteristic of Russian imperial gratitude.

Three days in an open galley near the Ukrainian port of Kherson was too much for the already feverish naval hero. Hurt and bewildered, he spent two weeks in bed with bronchial pneumonia.

On his return to St. Petersburg, further misery awaited the helpless man in the infamous and senseless Russo-German-girl-scandal, with which courtesan Catherine, in Puritan mockery, tortured her handsome Admiral.

Having wasted his health and his talents in sixteen months of Russian service, Paul Jones asked for and was granted a two year leave of absence. His "retreat from Russia" was made in good order with a "hail the conquering hero" reception in Vienna. May of 1790 found him esconced in a pleasant little house and garden of his own on the Rue de Tournon hard by the Luxembourg. France, already experiencing labor pains preceding the birth of her Revolution, got but little help from the exhausted man. Yellow and emaciated, lonely and sad, the Admiral confined himself to the seasoned joys of a few groups of old admirers. Latterly, he spent his days lying in the garden hammock or sitting in a favorite easy chair in his room. Affectionate respect was his from both the old and the new order in France, and the Revolution touched him but lightly. Social activity became increasingly

SURGERY, GYNECOLOGY AND OBSTETRICS

difficult for him, owing to frequent and exhausting coughing episodes and to encroaching dropsy. Repeated exposure to cold, stormy weather had affected his respiratory system. The intermittent fevers which had attended him ever since his tropical days had injured his kidneys. The frustrations of a brilliant life had strained his dauntless spirit. Like a ship, sturdy and well built, being broken up prematurely on the rocks of misfortune. Disappointment with light, repeated strokes tortured both body and soul. His spirit had always been strained by a sort of split personality—a clash of the energetic seacaptain (the extravert) with the intensive but unexpressed poet (the introvert).

When Madame Arbergne, his housekeeper, entered his room at about nine o'clock on the evening of July 18, 1792, Death had preceded her. The Admiral lay face downward across the middle of his couch, with his feet on the floor. His arms were outstretched, one hand clutching the counterpane, the other clasping his beautiful watch, gift of the friendly Duchess of Chartres. Gouverneur Morris, then American ambassador to France, had witnessed his will just three hours before, at the end of a quietly happy afternoon spent with friends in the garden. The attending physician was the great anatomist, Vicq d'Azyr, Marie Antoinette's doctor, and permanent secretary of the Paris Academy of Medicine.

The French Assembly, then sitting, passed a unanimous resolution honoring the memory of Paul Jones, "Admiral of the USA" and decreed that twelve of its members should assist at the funeral. Some even proposed that he be buried in the Panthéon with the illustrious dead of France. But Admiral Jones' body was laid in a cemetery for foreign Protestants, having been put into a leaden coffin, "that, in case the United States should claim his remains, they might be more easily removed." A letter found in the French National Archives of 1792 states that "M. Simoneau has furnished the cost of interment of Admiral Paul Jones, of which the bill amounts to 462 francs."

If he had lived a week longer, Jones would have become an Admiral of France with authority to reorganize the French Navy. Had he lived three weeks longer, he would have received from George Washington orders to take charge of the complicated American interests in European waters, especially those connected with the Barbary pirates. For one hundred and thirteen years, the body of America's first naval hero lay forgotten in the

little cemetery of St. Louis, which became successively a garden, a dumping ground, the site of a laundry, and of several other squalid buildings. Two unsuccessful attempts to locate the grave were made, but it was not until 1905 that Ambassador Horace Porter, by a long and pains-taking examination of cemetery records, city maps, and documents, was able to trace the burial place. Five shafts were sunk with galleries in all directions. The intervening spaces were probed by long iron rods. Five leaden coffins were found, of which the third was superior in solidity and workmanship. It contained a well-preserved male body packed in hay, straw, and what had probably been alcohol. Clothed in a winding sheet and linen shirt, the body had its long hair gathered into a monogrammed cap. The flesh was still intact.

Identity was proved by (1) the striking resemblance of the features to the medal made by Dupré, voted by Congress in 1787, (2) anthropologic agreement of measurements with those of the bust of Jones made by Houdon, (3) length of the body, color of the hair, peculiar formation of the ear, and condition of the teeth, (4) the cap marked with the initial "J" made with the loop so rounded as to form a "P" when inverted, (5) the autopsy showing that the subject had had pneumonia and interstitial nephritis.

Dr. Capitan made the autopsy, opening the body from the back in order not to change the appearance of the corpse. He found the viscera much contracted but well preserved. The lungs showed pleural adhesions, especially in the upper lobe. When cut open, they showed a brownish parenchyma. The surface and interior pulmonary tissue presented small white hard masses, three to four millimeters in diameter, somewhat like calcified tubercles. These were particularly prevalent at the level of the diaphragmatic edge of the lower lobe. The heart was grossly normal, but with some flat concretions *sous-endocardiques*, similar to those of the lungs. The liver was a yellow-brown. The healthy gall bladder contained a pale yellow-brown pasty bile. The stomach was very small and contracted. The spleen seemed large in comparison with the other viscera. Both kidneys were small, hard, and contracted. The intestines were contracted and empty. The head was not opened.

Histologic studies revealed a normal heart, with muscle fiber streaks. The seemingly normal liver did not show the cellular lesions expected from the known symptoms of jaundice. The white granulations in the lungs appeared to be tyrosin crystals, products of the decomposition

VINCENT DEATH COMES FOR THE ADMIRAL

of azotized substances. No tubercle bacilli could be demonstrated, but there were found small rounded masses, partly calcified, corresponding to patches of bronchopneumonia. The kidney sections showed chronic interstitial nephritis, with thickened vessel walls invaded by sclerosis. Some glomeruli had changed into fibrous tissue in the shape of small spheres.

From the July 19, 1905 edition of the Paris *Le Temps* comes the following

"We know that the celebrated sailor had manifested some very grave pulmonary symptoms toward the close of his life, and that they were localized in the left lung. Further, that sometime before his death, he had had dropsy of the lower extremities, descending to the feet and ascending to the abdomen, indicating also a renal affection. The autopsy of the cadaver showed the organs impregnated with an alcoholic liquid, contracted, brownish, but so well preserved that Prof. Cornil was able to make histological sections, identical with those of the viscera obtained in an autopsy of our own times. The microscopic examination showed with the greatest exactness, that the liver was normal, that there existed in the left kidney especially, foci of the glomeruli, indicating an advanced interstitial nephritis. These histological lesions accord thus perfectly, we see, with the clinical signs presented toward the end of his life by Jones. It is remarkable that this is the first time that the identification of a cadaver has been realized, by means of these diverse methods, a century after the death of the subject."

The body was brought to Annapolis with due ceremony, and commemorative exercises were held in the Naval Academy's Bancroft Hall on April 24, 1906. There the body rested ignominiously for seven years on a couple of wooden saw horses behind a stairway. On January 26, 1913, one hundred and twenty one years after death, the Admiral's body was finally placed in the crypt of the new Naval Chapel. Cut into the marble of the mausoleum are the names of seven of his ships, including the *Ranger* and the *Bonhomme Richard*.

Napoleon, musing gloomily over Trafalgar, was heard to ask, "How old was Paul Jones when he died?" "Forty-five" was the answer. "He did not fulfill his destiny. Had he lived to this time, France might have had an admiral."

REVIEWS OF NEW BOOKS

FROM the large volume of material at the Memorial Hospital and the author's wide experience with tumors of bone, Dr Coley¹ has compiled an informative book which should lead to earlier diagnosis and better treatment. The author stresses primarily the clinical, diagnostic, and therapeutic aspects of the diseases described. The value of the text might have been enhanced by a more complete correlation of the pathologic aspects of bone tumors with their clinical and therapeutic aspects.

The book *Neoplasms of Bone* is organized into sections, and most sections may be profitably read with little reference to the rest of the book. Each section has its own bibliography appended which adds to the completeness of the subject material. Such a division of material into self-contained sections has led to minor overlap of the sections on surgical and constitutional therapy and part of the section on radiation therapy.

The illustrations, including roentgenograms, photomicrographs, drawings, and statistical tables, in general are numerous and excellent. Illustrative cases are abundantly cited, frequently in detail. The index is large and well chosen.

The author's classification of bone tumors is a modification of the revised classification of the Bone Sarcoma Registry of The American College of Surgeons. Bone tumors are defined as new growths arising in bone or derived from cells which are components of skeletal tissue. They are divided into benign and malignant types and are classified for the most part according to the cell or tissue of which they are composed, as chondroma and chondrosarcoma. However, the term osteogenic sarcoma, instead of being limited to bone forming sarcoma, is sometimes used later in the text in Ewing's original sense to indicate sarcoma arising in bone, consequently the osteolytic osteogenic sarcoma and the term Ewing's sarcoma is used in the original sense to indicate a specific lesion, endothelioma of bone, and next to osteogenic sarcoma is considered the most common primary tumor of bone. But there is now a large body of evidence that true endothelioma of bone is a comparatively rare lesion and that the great majority of tumors which Ewing described under this head are other types of cancer, as mesenchymal cell sarcoma, reticulum cell sarcoma, neuroblastoma, round cell fibrosarcoma, and other little differentiated sarcomas.

The various theories of cancer etiology are briefly described. The differential diagnosis of bone lesions and a diagnostic survey of such lesions is well done.

NEOPLASMS OF BONE AND RELATED CONDITIONS. THEIR ETIOLOGY, PATHOGENESIS, DIAGNOSIS AND TREATMENT. By Bradley L. Coley, M.D. New York: Paul B. Hoeber, Inc. 1949.

This includes a discussion of the indications and contraindications of surgical and aspiration biopsy and the technique of each. Relatively few clinics rely upon aspiration biopsy in bone sarcoma to the extent which the author advocates.

There is an excellent chapter by Woodard on blood chemistry in the diagnosis of diseases of bone. It includes a table summarizing the chemical findings in typical cases of bone neoplasms and in non neoplastic diseases. Especially interesting are the studies correlating alkaline and acid phosphatase levels to primary and metastatic bone tumors.

The benign tumors and tumor-like lesions of bone are covered with considerable detail. However, the discussion of such non-neoplastic lesions as solitary bone cyst, fibrous dysplasia of bone, chondrocytoma, osteogenic fibroma congenita and so-called non trophic calcifications under benign tumors may serve to link them too closely with the latter. The chapters on chondroma, chondroblastoma, and giant cell tumor are particularly good. The importance of benign tumors, especially chondromatous tumors, as precursors of malignant tumors, is duly considered.

The primary and metastatic tumors of bone are dealt with concisely. The author expresses the desirability of classifying osteogenic sarcoma into 3 groups—osteogenic sarcoma, chondrosarcoma, and fibrosarcoma—to avoid the confusion of further subdivision, but this runs counter to strict classification according to tissue type. A thorough analysis of 283 cases of osteogenic sarcoma seen and treated at Memorial Hospital is presented. Ewing's tumor, reticulum cell sarcoma, angiosarcoma, and multiple myeloma are similarly analyzed according to clinical features, sex, age incidence, location, treatment, and survival rate. The types and effectiveness of treatment are discussed with each tumor group and again, in more detail, in the special chapters and under surgical and radiation therapy. Of considerable importance is the stress the author gives to the development of osteogenic sarcoma following irradiation. He advises against the use of irradiation therapy for benign lesions for this reason. Amputations are well discussed, including end-results, and treatment of selected cases of bone sarcoma by resection and bone transplantation is properly advocated.

Sections on tumors involving bone by extension, metastatic tumors involving bone (numerically greater than primary bone tumors), tumors of bone in special localities, and lesions of the skeletal system that may simulate neoplasms of bone add to the completeness of the book. Of the latter group the most important under consideration are myositis ossificans, which is all too often confused with osteogenic sarcoma, and Paget's disease in which sarcoma frequently develops.

REVIEWS OF NEW BOOKS

This book should be popular with both practitioners and medical students alike

DALLAS B. PREMISTER.

THERE is nothing finer in medical literature than the sincere appreciation of the achievements and contributions of those who built the foundations on which modern medical practice is based. When, as has often happened, the builders have had to work alone, and with too little understanding and sympathy from their contemporaries the important part they played may easily be forgotten. For that reason in particular we are under obligation to those who have recorded the story of the pioneers in medicine and surgery and made us aware of our indebtedness to men whose teachings and ideas we constantly apply, perhaps with little thought of their source or little appreciation of our obligation.

In a small and exceedingly interesting volume of 250 pages H. Winnett Orr has told the story of Hugh Owen Thomas, of his nephew, Sir Robert Jones, and of the American orthopedic surgeon, John Rudlon, who made American surgeons aware of Thomas and of his fundamental contributions to surgery. A very thoughtful and scholarly chapter by Arthur Steindler on Rudlon and his share in molding orthopedic surgery and an extensive bibliography add to the completeness and to the value of Dr. Orr's contribution.

Two factors in Thomas' contribution to surgical practice stand out with particular clarity: his constant and persistent emphasis on rest, "enforced, interrupted and prolonged," and the skill with which he devised methods of providing that rest. That Thomas was a general practitioner and that his application of surgical principles was carried into every phase of his practice is often forgotten by those who think of him only as the originator of the Thomas splint. Orr recalls that Sir Arthur Keith in his interesting essay on Thomas stressed his application of the principle of rest in the treatment of intestinal obstruction rather than in the field with which we invariably associate his name. That important principle of complete rest in the treatment of fractured bones and joint disease is concisely expressed in two quotations from Thomas' small volume, *Diseases of the Hip, Knee, and Ankle Joints*, quoted in Dr. Orr's preface (p. ix).

"I assert that a fractured thigh, if treated by extension only, would be accompanied by vastly more muscular irritability than if the same case was placed in a modern appliance with retention, in which the limb was retained and fixed immovably."

"Efficient and enforced rest in joint disease as well as in fractures, is the infallible remedy for quieting the irritated muscles, not extension."

ON THE CONTRIBUTIONS OF HUGH OWEN THOMAS OF LIVERPOOL, SIR ROBERT JONES OF LIVERPOOL AND LONDON, JOHN RUDLON M.D. OF NEW YORK AND CHICAGO TO MODERN ORTHOPEDIC SURGERY. By H. Winnett Orr M.D. with a supplement on Rudlon and his share in moulding orthopedic surgery by Arthur Steindler M.D. Springfield Ill. Charles C. Thomas, 1949

It is interesting to quote beside Thomas' words the author's own comments, on page 25:

"We do not seem to have arrived at this 'rest' point of view for the acutely inflamed fractures and compound fracture wounds. There is still the attempt to diminish the amount of apparatus, to provide more joints and mobility, to make our patients ambulatory, and to render less efficient rather than more so the kind of control which Thomas described long ago as rest, 'enforced, uninterrupted and prolonged'."

It is this basic principle and the most effective method of securing it to which Orr constantly returns in this study of the three men.

The "Surgery" of Hugh Owen Thomas at 11 Nelson Street in Liverpool in which his nephew, Sir Robert Jones, was associated and in which Jones and his pupils continued their work in later years has often been referred to. Close to the consulting rooms was the brace shop with its smithy, its saddler, and skilled workers. Here it was that Thomas and his aids fashioned the splints and braces that enabled him to provide for his patients the rest upon which he was so insistent. So complete was the equipment and so skilfully designed the splints which he devised, that in Sir Frederick Watson's words, "No matter from what distance a patient comes, no matter whether the affection be spinal caries, hip disease, or fractured thigh, he is always able to return home in an hour or so, most accurately fitted with a simple and appropriate splint."

The work of Jones and of Rudlon is better known to the present generation of American surgeons than that of Thomas. Jones "made acceptable to the profession" the principles which Thomas insisted upon so uncompromisingly. His tact, his diplomacy, and his genius for friendship enabled him to reach a wide and influential audience and to place the specialty of orthopedic surgery in Great Britain upon a firm foundation. Rudlon also, was a powerful influence in American orthopedic surgery during the 40 years that followed the formation of the American Orthopedic Association in 1887. As Dr. Steindler says:

"John Rudlon may be said to represent the connecting link between the American tradition and the rising British influence of such masters as Hugh Owen Thomas and Sir Robert Jones. When he died in 1936 at the age of 84 he left an inspiring memory to his pupils. So sound had been his teachings, so careful, so deliberate, so conservative, and so thoughtful had been his approach to the difficult subjects or problems of our profession, that I do not think anyone of us really believes his methods antiquated nor would any of us hesitate to take counsel with him in any situation if he were alive today."

Everyone interested in orthopedic surgery can gain helpful stimulus and direction by reviewing anew under Dr. Orr's guidance the contributions of these three distinguished surgeons to the treatment of injuries and diseases of bones and joints.

SUMNER L. KOCH

SURGERY, GYNECOLOGY AND OBSTETRICS

THE elaborate two volume contribution *Lehrbuch der Geburtshilfe*¹ is written by one of the leading German obstetricians and gynecologists. In the first volume the author discusses the physiology of pregnancy, labor, the puerperium, and lactation, and he discusses multiple births, the healthy newborn infant, and prenatal care. In the second volume he takes up the pathology of pregnancy, dystocia in labor, the pathology of the puerperium, and disturbances of the newborn.

Very little literature is quoted either in the text or at the end of any chapter. This was done intentionally because Martius maintains that physicians who are interested in the literature should consult the large systems of obstetrics. There are 539 illustrations in the first volume and 486 illustrations in the second volume, a total of 1,025 illustrations. Nearly all are highly instructive and many are in color. However, most of the reproductions of x-ray pictures are so poor that they are almost useless. Throughout both volumes, the author reveals his extensive experience as an obstetrician and as a teacher. His attitude is conservative and in line with that of most obstetricians throughout the world. One minor criticism is that the description and illustration of the Credé maneuver for delivery of the placenta should have been omitted, because this procedure can do great harm. Martius himself emphasizes that this maneuver is "not entirely without danger." Another point of disagreement is the use of oxytocic drugs in cases of placenta previa treated conservatively. Even in a multipara with a marginal rupture of the lower uterine segment. Aside from these and other minor criticisms the book can be highly recommended to physicians who read German. Martius was assisted by Drs. W. Bickenbach and K. Nordmeyer, and all three deserve great credit for having written these books. The publishers also are to be commended because the paper is good, the type is very clear and all the illustrations except those of the roentgenograms have been reproduced admirably.

J. P. GREENHILL.

THE book *Die geburtshilflichen Operationen, Ihre Ausführung und Anwendung*² is the sixth edition to appear since 1934. In it the author discusses the structure of the birth canal and the baby, the mechanism of labor, forceps delivery, breech delivery, version and extraction, embryotomy, repair of lacerations, episiotomy, cervical incisions, pubiotomy, hydrostatic bags, abdominal cesarean section, delivery of twins, treatment of prolapse of the cord and arms, treatment of placenta previa, manual removal of the placenta, uterine tamponade, treat-

¹LEHRBUCH DER GEBURTSHILFE. By Prof. Dr. Med. Heinrich Martius. Assisted by Prof. Dr. Med. Werner Bickenbach, Prof. Dr. Med. Kurt Nordmeyer, and Kath. Droyen. Vol. 1: Physiologie. Vol. 2: Pathologie. Stuttgart: Georg Thieme, 1948.
²DIE GEBURTSHILFlichen OPERATIONEN. IHRE AUSFÜHRUNG UND ANWENDUNG. Ein Lehrbuch fuer Studierende und Gebrauchsueber AERZTE. By Prof. Dr. Med. Heinrich Martius. 6th ed. Stuttgart: Georg Thieme Verlag, 1948.

ment of abortion, curettage, induction of labor, and sterilization.

There are several minor points with which the reviewer disagrees. The metal hook for the delivery of a breech in a living baby should not be described or illustrated. Likewise the Credé maneuver for expelling the placenta should be condemned and the uterine pack should be given up for controlling bleeding from an atonic uterus. Twenty of the 287 pages and 27 of the 281 illustrations are devoted to destructive operations on the child. This is a disproportionate amount of space and number of illustrations for operations which are now fortunately seldom performed. The only form of tubal sterilization described is the Madlener, though it is our belief that the Pomeroy procedure yields better results. Aside from these few minor criticisms Martius has written an excellent book which will prove helpful to anyone who reads German. The fact that this is the sixth edition is ample proof that the book has been of great assistance to German students and physicians. The publishers have prepared this book exceedingly well as they have Martius' companion two volume book, *Lehrbuch der Geburtshilfe*.

J. P. GREENHILL.

THE authors present in the monograph *Cardiac Catheterization in Congenital Heart Disease*³ a brief statement of the methods employed and the information to be gained by cardiac catheterization in infants and children.

The first part of the book outlines the technique employed for the physiologic studies, shows x-ray observations during catheterization, blood pressure tracings within the heart and great vessels, and formulas for calculation of systemic and pulmonary blood flow and of blood shunts.

The second part of the book reports 17 illustrative cases in which clinical data and catheterization have been co-ordinated in the diagnosis of various types of congenital cardiac malformations.

It is an excellent book which will be read with interest and profit by those who wish to familiarize themselves with this highly specialized diagnostic procedure.

STANLEY GIBSON

THE second edition of *Operating Room Technique*⁴ by Edythe Louise Alexander is a comprehensive presentation of the problems involved in carrying on the surgical work of the hospital. The material is carefully organized and presented in detail. It is generously illustrated and includes a description of the anatomy involved, operative areas, surgical preparation of the skin, incisions, positions, and sterilization of material to be used in operative procedures.

³CARDIAC CATHETERIZATION IN CONGENITAL HEART DISEASE. A CLINICAL AND PHYSIOLOGICAL STUDY IN INFANTS AND CHILDREN. By Andre Cournaud, M.D., Janet S. Baldwin, M.D., and Aaron Himmelstein, M.D. New York: The Commonwealth Fund, 1949.
⁴OPERATING ROOM TECHNIQUE. By Edythe Louise Alexander. 2d ed. St. Louis: The C. V. Mosby Co., 1949.

REVIEWS OF NEW BOOKS

A chapter on the history of asepsis adds much to the interest of this subject. The author constantly emphasizes the fact that the welfare of the patient is the first consideration, and stresses the necessity of careful planning, co-operation, and teamwork. This volume can be profitably used as a guide and reference for operating room personnel.

HAZEL M. JOHNSON

THE author of *Plaster of Paris Technique* discusses the various forms of plaster used in surgery, giving in detail instructions for handmade plaster bandages. He includes the principles used in the care of the plaster and the application of the various types of plaster casts and a discussion of the errors and difficulties in plaster technique.

A chapter is devoted to the technique of pattern plaster and is well illustrated. The spine, the upper and the lower extremities are dealt with separately in sections. Several chapters are devoted to the use of plaster of paris in war surgery and one chapter is devoted to follow-up care. Approximately one-third of the book is text, the remainder consists of illustrations which are grouped at the end of each chapter. There has long been a need for a satisfactory text on plaster of paris technique. The brevity of only partially answers the purpose. The brevity of the text combined with the lack of correlation with the illustrations greatly reduces the effectiveness of the book.

ERWIN J. CUMMINS, JR.

THE standard *Textbook of Bacteriology*, first written by Hiss and Zinsser in 1910, has been repeatedly brought up to date through 8 editions, first by Zinsser and then by Bayne-Jones. The present group of authors, in preparing the ninth edition, have tried "to keep inviolate the basic biologic approach to bacteriology and at the same time to emphasize the public health significance and the practical clinical importance of certain of the biological characteristics of the organisms."

In preparing this review for SURGERY, GYNECOLOGY AND OBSTETRICS the writer has had in mind the value which this book might have for the surgeon, the gynecologist, and the obstetrician. Certainly the widening of the scope in these three fields of medicine has depended largely on the development and growth of the science of bacteriology. Zinsser himself believed in the close association of his laboratory with the clinical departments, and the present authors, as noted above, clearly expressed their intention of stressing the "practical clinical importance" of the knowledge of bacteria to all departments concerned with infection.

The book is divided into 77 chapters covering a historical review and sections on general bacteriology

PLASTER OF PARIS TECHNIQUE By E. O. Geckeler, M.D. F.A.C.S. 4th ed. Baltimore: The Williams & Wilkins Co. 1948.
ZINSSER'S TEXTBOOK OF BACTERIOLOGY Revised by David T. Smith, M.D., Donald S. Martin, M.D. M.P.H. Norman F. Conant, Ph.D., Joseph W. Beard, M.D. Grant Taylor, M.D. Henry J. Kohn, Ph.D. and Mary A. Poston, M.A. 9th ed. New York: Appleton Century Crofts, Inc. 1948.

and immunology. Then the various pathogenic groups are described with special emphasis on the spirochete, the pleuropneumonia group, the rickettsiae, the viruses, and the mycoses. In these chapters reference is made to the clinical manifestations of these organisms. However, the surgeon, gynecologist, and obstetrician would like to see more detailed discussion of the relationship of bacteriology to the operating and delivery rooms, the minutiae of the processes of sterilization and sterile technique, the methods of minimizing the contamination of the "sterile field," and a consideration of carriers of bacteria among operating and delivery personnel. They would also like to see a discussion of the clinical activity of the streptococcus, staphylococcus, pneumococcus, gonococcus, the tubercle bacillus, the aerobic gram-negative rods, the gas gangrene clostridia and the other anaerobic organisms in their clinical fields of interest. These are only lightly touched upon. Furthermore, hardly any reference is made to the work which has been accomplished before, during, and after World War II in the many laboratories of surgical bacteriology. It is hoped that in future editions these practical points will be more fully covered.

FRANK LAMONT MELENEY

THE fourth edition of *Fractures and Dislocations* is divided into two sections. The first section deals with fractures, 7 chapters being devoted to general consideration and principles of care. Fractures of the various bones or groups of bones are dealt with individually in the remaining chapters of the first section.

Part 2 deals with dislocations and is similarly organized. The author recognizes the usefulness of more than one method for the treatment of certain fractures but continues to recommend the one method of which he considers the simplest and most reliable for the best functional results. The text material is well organized and well written. Illustrations are excellent, conveniently placed, and referred to frequently in the text. The new developments in traumatic surgery which occurred since the third edition are included in the appropriate chapters. The book effectively fulfills its purpose for the general practitioner.

ERWIN J. CUMMINS, JR.

THE technique of retropubic prostatectomy is presented in a monograph of 95 pages entitled *L'Adenomectomie prostatique retro-pubienne* by R. Couvelaire. Many of the problems which are encountered in the performance of this operation are considered, and effective technical methods for their solution are presented. Although the author's technique differs in many minor respects from the excellent method of Terence Millin, the originator of the operation in its present form, the book is well written and concise.

**FRACTURES AND DISLOCATIONS FOR PRACTITIONERS.* By Edwin O. Geckeler, M.D. F.A.C.S. 4th ed. Baltimore: The Williams & Wilkins Co., 1948.
**L'ADENOMECTOMIE PROSTATIQUE RETRO-PUBIENNE* By R. Couvelaire. Paris: Editions Bernard Bacchet, 1948.

SURGERY, GYNECOLOGY AND OBSTETRICS

This otherwise excellent volume, which is in the form of an atlas and well printed upon glossy paper of good quality, suffers from the poor quality of its illustrations. The numerous photographs are often out of focus and poorly finished, and they frequently fail to demonstrate significant anatomic landmarks. The drawings are also very sketchy and of inferior quality.

FREDERICK A. LLOYD

THE textbook of surgery for the eye physician *Surgery of the Eye*¹ by a master eye surgeon is a concise and complete treatment of the subject in 392 pages. The details of each step in the surgical procedures are given and aided by the use of many illustrations and diagrams. The contents include first the general considerations for the eye surgeon, preparation of the patient, and a detailed description of the use of local anesthetics. Postoperative treatment includes the use of typhoid-paratyphoid in large doses to which great credit is given. With the varied antibiotics now available such frequent use of foreign proteins in such large doses should be carefully considered.

The operative procedures carefully described include paracentesis, intracapsular and extracapsular extraction of the lens with the management of complications. All of the standard operations for glaucoma are given with the management of complications. Other chapters include the operations on the retina, sclera, cornea, conjunctiva, lids, and sockets including the plastic procedures. The treatment of intraocular foreign bodies is outlined in detail. Surgery for ptosis is considered according to the shortening or advancement of the levator muscle, utilizing the occipito frontalis or the superior rectus muscles. The surgery on the extraocular muscles gives the technique of Todd, Jameson, and Reese which was described by White and later by Berens. The surgery on the inferior oblique at its insertion is not mentioned nor is the more recent surgery on the superior oblique. The book concludes with the description of operations on the tear apparatus. It is an excellent book and all eye surgeons would be better for reading it or referring to it before the usual or any unusual procedures that they are called upon to do.

BEULAH CUSEMAN

WITHOUT a doubt *Cancer Metastases*² by Hans Walthers is one of the finest books of its kind. The author, a roentgenologist, had often encountered cases in which tumor metastases were demonstrable in the bones, the lungs, and in other areas, while the seat of the primary tumor remained unknown. The desire to show a relationship between the location of the original tumor and the seat of the metastases led to a careful study over a 15 year period of the material of the Pathologic Institute at Zurich.

¹SURGERY OF THE EYE By Meyer Wiener M.D. 2d ed. New York: Grune & Stratton 1949.
²KREBSMETASTASEN By Dr. Med. Hans E. Walthers Basel Benno Schwabe & Co. 1948 (Imported by Grune & Stratton Inc. New York.)

³HANDBOOK OF SURGERY By Eric C. McKie M.B. Ch.B. F.R.C.S. (Edin.) F.I.C.S. and Ian Mackenzie M.B. Ch.B. F.R.C.S. (Edin.) Foreword by the late Sir John Fraser Bart. M.C. M.D. Ch.M. F.R.C.S. (Edin.) 2d ed. Baltimore: The Williams & Williams Co. 1949.

The author has come to the conclusion, and brings abundant proof of the fact, that the spread of tumor metastases always follows the established vascular and lymphatic pathways, and obeys the laws of circulatory physiology. Retrograde transport by reversal of the lymph flow, spread from organ to organ by way of lymphatic channels, and other bizarre explanations for the apparently paradoxical spread of some metastases are vigorously denied. The concept of micrometastases in the lungs, which subsequently lead to a dissemination through the arterial circulation, is a very interesting one, and not only serves to explain many of the pathways of tumor metastases, but also readily lends itself to microscopic proof. The author has established certain rules for hematogenous metastases and divides them into four main types.

This volume throughout gives evidence of great scholarship and a painstaking evaluation of clinical and pathological material. It is printed upon glossy paper of good quality with clear, easily readable type. The illustrations are beautiful and the photography is excellent. The photomicrographs are especially noteworthy and demonstrate a superb histologic technique. This book is a classic in its field and should serve as a standard reference for the clinician as well as the pathologist.

FREDERICK A. LLOYD

THE *Handbook of Surgery*³ written by McKie and Mackenzie is a fine compendium consisting of 41 chapters in 764 pages covering the field of general surgery. Written by teachers of wide experience who obviously know the requirements and limits of a handbook, it is concise but not at the cost of being inadequate. Designed to be of greater value to the senior undergraduate who is interested in a comprehensive review of the essential and important aspects of surgery it has much to offer to both the surgeon and the general practitioner. The chapters follow the pattern of first, a brief discussion of development, anatomy and physiology, followed by symptoms, pathology, clinical examination, treatment, then complications and their treatment. Some chapters have the valuable addition of a section of interpretations of roentgenographic and other clinical laboratory findings, and of a discussion of common errors of interpretation. While any description or discussion of operative techniques is wisely avoided the common generally accepted surgical procedure is named. The orthopedic division, Chapters 30 through 41, is unusually well presented in a book of this design and scope. The book is new and up to date, but also follows the time proved fundamental principles of surgery. It is a worth while addition to the surgery texts.

RUSSELL T. BORTH

REVIEWS OF NEW BOOKS

results were obtained by bed rest, dehydration and osmotherapy
 GEORGE PERRET

THE author, the professor of surgery at the University of Kiel, reviews in the 190 page monograph entitled *Pathologische Physiologie der frischen, geschlossenen Hirnverletzung, insbesondere der Hirnerschuetterung*¹ the literature on closed cerebral injuries and his own experiences with such injuries. He found that the majority of the patients who died of cerebral concussion had severe circulatory and vascular changes in the internal organs and especially the lungs. He describes a "centrogenic" pulmonary hemorrhage which he found to be caused by lesions in the hypothalamic region. Carefully evaluated animal experiments also revealed the same changes. Similar circulatory changes and hemorrhages in the heart, the liver, the kidneys, the pancreas, the spleen, and the lungs could be produced by small puncture lesions in the hypothalamic nuclei, and he concluded that the hypothalamic nuclei were the seat of a sympathetic and parasympathetic center which regulated peripheral circulation. Lesions of this center produced the peripheral circulatory changes which resulted in death.

He studied the various clinical changes which followed closed craniocerebral injuries and correlated them with experimental findings. Blood pressure, blood picture, blood distribution, respiration, body temperature, protein and carbohydrate metabolism, electrolyte and fluid balance, basal metabolic rate showed reversible postconcussion changes which were thought to be the result of stimulation of the sympathetic and parasympathetic center or of its pathways in the brain stem.

Posttraumatic symptoms and findings are also discussed, they include chapters on headaches, vertigo, oculomotor disturbances, temperature and blood pressure changes, and changes in bladder, sexual, vasomotor and metabolic function. Chronic posttraumatic disturbances were present in 30 per cent of the cases. They depended to a large extent on the pretraumatic personality of the patient himself.

Another chapter deals with the morphologic and functional findings of the injured brain and especially the etiology and pathology of cerebral swelling and edema causing posttraumatic increased intracranial pressure. Cerebral contusion, petechial and massive intracerebral hemorrhages are also mentioned. Spinal fluid, encephalographic and ventriculographic findings are discussed and their common relation to the development of cerebral edema arising on the second and third posttraumatic day is demonstrated. Arteriograms showed contraction of the cerebral vessels in concussion while they usually showed widened and poorly filled vessels in cases of contusion.

In his last chapter, the author discusses the prognosis and the treatment of fresh craniocerebral injuries, the indication and effect of dehydration, osmotherapy, spinal or ventricular puncture and surgical intervention are briefly presented. His best

IN the third edition of a paper bound monograph, *Technique de la chirurgie du sympathique et de ses infiltrations*², Doctors O Lambret, P Razemon, and P Decoux have presented an interesting discussion of techniques for various forms of sympathectomy and for use of novocain block. It should afford valuable reading for those interested in this field of surgery. Not included in the book are several of the newer procedures recently developed and often employed. However, included in it are interesting and apparently accurate drawings of the relationships of the sympathetic nerves and their ganglionated paravertebral chains to surrounding structures. It should prove interesting reading for those familiar with the French language and familiar with standard techniques for sympathectomy and the indications for use of block or excision of the ganglia and sympathetic chains.
 KEITH S GRIMSON

THE text *Pulmonary Tuberculosis*³ was first presented in 1939. The second edition has been completely revised, enlarged, and modernized. The task of revision has been the lot of W Pagel since Laurence O'Shaughnessy met death while in military service in 1940, and Gregory Kayne succumbed to illness in 1945. Dr Pagel has felt the loss of his stimulating partners, but has met the situation with the aid of carefully selected coauthors (F A H Simmonds, N Macdonald, and L Fatti). These men, in a splendid co operative venture, have dedicated their edition to their lamented confreres.

The pathological, clinical, and surgical aspects of pulmonary tuberculosis, including current concepts of antibiotic therapy, are presented. An extensive bibliography and usually a chapter summary is found at the end of each section. This group of Middlesex England physicians has compacted into this 720 page volume most of the essential information regarding pulmonary tuberculosis. The disease is thoroughly though concisely presented, controversial points are discussed with an open mind. Anyone interested in the field of tuberculosis will find this book of value.
 EUGENE L WALSH

GOOD books in English on ocular histology and pathology for reference and study have been sadly lacking in the past. The few that have been available are either out of date or very incomplete. The result is that the subject of ocular pathology has been neglected by a large number of practitioners and students of ophthalmology.

¹TECHNIQUE DE LA CHIRURGIE DU SYMPATHIQUE ET DE SES INFILTRATIONS. By O Lambret P Razemon and P Decoux 3d rev ed Paris G Dion & Cie 1948
²PULMONARY TUBERCULOSIS PATHOLOGY DIAGNOSIS MANAGEMENT AND PREVENTION. By G G Kayne, W Pagel, and L O'Shaughnessy 2d ed rev and partly rewritten by Walter Pagel, MD F A H Simmonds MA MD DPH N Macdonald, MB MRC P (Ed) and L Fatti FRC S London, New York and Toronto Geoffrey Cumberlege Oxford University Press, 1948

¹PATHOLOGISCHE PHYSIOLOGIE DER FRISCHEN GESCHLOSSENEN HIRNVERLETZUNG INSBESONDERE DER HIRNERSCHUETTERUNG KLINISCHE ANATOMISCHE UND EXPERIMENTELLE BEFUNDE By R Wanke Stuttgart Georg Thieme, 1948

SURGERY, GYNECOLOGY AND OBSTETRICS

Thanks to Professor Sommers, who is well qualified by many years of experience in working with and teaching the subject of ocular pathology, there is now available a satisfactory treatise on the subject. His book *Histology and Histopathology of the Eye and its Adnexa*¹ is divided into three parts. Part 1 has to do with normal histology, embryology, and senescence, Part 2 with general pathology (from an ocular viewpoint), and Part 3 with histopathology of the eye. This covers very well the various structures of the eyeball and adnexa. In addition, there are valuable chapters on ocular developmental abnormalities, glaucoma, myopia, injuries, and the pathologic conditions that arise as the result of surgery.

¹HISTOLOGY AND HISTOPATHOLOGY OF THE EYE AND ITS ADnexa. By I G Sommers M D. New York: Grune & Stratton 1949.

At the end of each chapter, under the heading "Reading of Source Material" there are remarks on the pertinent discussion by many authors, taken from their writings. This is one of the most interesting and valuable parts of the book. It contains a wealth of information and should act as a stimulus for further study by the reader. The book is well printed and illustrated. Perhaps more illustrations could have been used to advance the subject is complex and difficult and the reading of it makes for tough going at times. The ophthalmologist will be well repaid in the development of his understanding of his clinical problems for the effort that is required in a careful study of Sommer's excellent and exhaustive work.

DERRICK VAIL.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

- American College of Surgeons, Clinical Congress, Preliminary program for 35th, The Stevens, Chicago, October 17 to 21, 1949, 124, 249, 373, 492
- Amputation, Suction socket for above knee amputees, 335, Extension of primary neoplasms of bone to bone marrow, 704
- Anatomy, Abdominoperineal removal of low lying cancer of rectum, 5 year cures and local recurrences, 31, art, Anatomical tabulae and initial letters in Vesalius' *Fabrica* and in imitative works, 96, Posterior sub-sphincteric space, its relation to posterior horseshoe fistula, 222, of hernial regions, I Inguinal hernia, 417, II Femoral hernia, 752
- Anemia, macrocytic, Observations on, associated with pregnancy, 76, Primary splenic panhematopenia, 79
- Anesthesia, procaine, Continuous lumbar paravertebral sympathetic block maintained by fractional instillation of procaine, 447
- Anesthetic agents, Predisposing action of, on vascular responses in hemorrhagic shock, 469
- Anus, Posterior sub-sphincteric space, its relation to posterior horseshoe fistula, 222
- Appendicitis, experimental, Morbid factors in, 165
- Appendix, gangrenous, Morbid factors in experimental appendicitis, 165
- Arteries, occlusion, Studies on effects of concomitant venous ligation in acute, 722
- Ascites, Experimental, effects of sodium chloride and protein metabolism of dogs with constricted inferior vena cava, 529
- Aureomycin, treatment of urinary tract infections, 43
- Auricular appendage, fibrillation, Removal of, in dog, 623
- Axilla, radical dissection, Regional lymph node dissection in cancer of extremities, 591
- BACITRACIN, Efficacy and safety of systemic administration of, in various types of surgical and certain medical infections, with analysis of 270 cases, 657
- Bile duct common, Study on relief of obstruction in, and in papilla of Vater, 49, Analysis of postoperative cholangiograms, 292, extrahepatic, Carcinoma of, 429, Repair of common, over buried catheter, 454, Comparison of pain produced experimentally in lower esophagus, common, and upper small intestine with pain experienced by patients with diseases of biliary tract and pancreas, 573
- Biliary tract, Comparison of pain produced experimentally in lower esophagus, common bile duct, and upper small intestine with pain experienced by patients with diseases of, and pancreas, 573
- Bladder, Vesicointestinal fistulas, 411
- Block, lumbar paravertebral sympathetic, Continuous, maintained by fractional instillation of procaine, 447
- Blood, and "available fluid" (thiocyanate) volume studies in surgical patients, Part I Normal patterns of response of, volume, available fluid, protein, chloride, and hematocrit in postoperative surgical patient, 9, Observations on macrocytic anemia associated with pregnancy, 76, Primary splenic panhematopenia, 79, loss, and "available fluid" (thiocyanate) volume studies in surgical patients, Part II Operative and postoperative, with particular emphasis upon uncompensated red cell loss, 181, hypoprothrombinemia, effect of moderate degrees of dicumarol induced, on experimental intravascular thrombosis, 339, Rh factor, ed 362, Some aspects of development of intrathoracic surgical thrombosis and embolism, 640, circulation, Artificial, Mechanical heart-lung system, 684, coagulation, Abnormal bleeding, II Further clinical experience with toluidine blue and protamine sulfate, 692, circulation, Cerebral, flow and metabolism in toxemias of pregnancy, 715, peripheral circulation, Studies on effects of concomitant venous ligation in acute arterial occlusion, 722, coagulation, Observations on clotting mechanism in menstruation and menorrhagia, 764
- Blood pressure, Effect of reduced blood flow to liver in renal hypertension, 360
- Blood transfusion, Ultrarapid, clinical and experimental observations, 442
- Blood vessels, intestinal, Predisposing action of anastomosis, 393, peripheral, Predisposing action of anastomosis on vascular responses in hemorrhagic shock, 469
- Bone, sarcoma, Ewing's tumor, 209, tuberculosis, Streptomycin in skeletal, ed 244, Behavior of, grafts, 310, strength, of cancellous, Determination of, in head and neck of femur, 439, transplant, bank, ed 485, graft, Treatment of slipping of upper femoral epiphysis, study of results of 42 cases, 559, healing, Effect of intramedullary nailing on healing of fractures, experimental study, 609, Fractures of long, ed 643, Extension of primary neoplasms of, to, marrow, 704, tumors, lytic, Eradication of benign, and immediate reconstructive surgery with emphasis on benign giant cell tumors, 735
- Bone bank, ed 485
- Bone marrow, Extension of primary neoplasms of bone to, 704
- Book Shelf, Anatomical tabulae and initial letters in Vesalius' *Fabrica* and in imitative works, 96 Birth of emperor, 366, Death comes for admiral, 778
- Brain, Unilateral prefrontal lobotomy for relief of intractable pain and termination of narcotic addiction, 385, Some aspects of development of intrathoracic surgery, 629
- Breast, Papilloma of lacteal duct, 345, Multiple primary cancer, study of 36 patients, 767
- Bronchiectasis, study of segmental distribution of pathologic lesions, 145
- Bronchus, Bronchiectasis, study of segmental distribution of pathologic lesions, 145
- CANCER, Cytologic diagnosis of, of descending colon and rectum, 24, Abdominoperineal removal of low lying, of rectum, 5 year cures and local recurrences, 31, diagnosis, Cytological, in transudates and exudates, comparison of Papanicolaou method and paraffin block technique, 478, Regional lymph node dissection in, of extremities, 591, Multiple primary, study of 36 patients, 767
- Carcinoma, Treatment of, of vulva, ed 242, of thyroid gland, 349, Diagnosis of preinvasive, of cervix, 405, of extrahepatic bile ducts, 429, in situ, Histochemical studies on glycogen in, of cervix uteri, 616

Heparin, Clinical studies of, cofactor, 20, Production and prevention of thrombosis and embolism, 640
 Hernia, inguinal, Criteria, classification, and technique of iliopectineal (Cooper's) ligament hernioplasty, 227, inguinal, Anatomy of hernial regions, I, 417, inguinal, Simultaneous prostatectomy and inguinal herniorrhaphy, 621, femoral, Anatomy of hernial regions, II, 752
 Hernioplasty, Criteria, classification, and technique of iliopectineal (Cooper's) ligament, 227
 Herniorrhaphy, inguinal, Simultaneous prostatectomy and, 621
 Hospital, modern, Bone bank, ed 485
 Hyoid bone, Thyroglossal tract abnormalities—cysts and fistulas, report of 105 cases from Johns Hopkins Hospital observed between years 1926 and 1946, 727
 Hypertension, Peptic ulcer following splanchicectomy, report of 13 cases, 271, renal, Effect of reduced blood flow to liver in, 360
 Hysterectomy, abdominal, vaginal, Indications for, ed 92, Vaginal, ed 94, Vaginal, 191

INFANTS, newborn, Rh factor, ed 362, newborn, Congenital deformities of feet, ed 487
 Infection, Aureomycin treatment of urinary tract, 43, Efficacy and safety of systemic administration of bacitracin in various types of surgical and certain medical, with analysis of 270 cases, 657
 Inguinal region, Anatomy of, I Inguinal hernia, 417, II Femoral hernia, 752
 Instruments and apparatus—suction socket prosthesis, Suction socket for above knee amputees, 335, for rapid blood transfusion, Ultrarapid blood transfusion, clinical and experimental observations, 442, to oxygenize blood, Some aspects of development of intrathoracic surgery, 629, nail plate for ingrown toenail, Simplified treatment of ingrown toenail, 638, for artificial circulatory system, Production and prevention of thrombosis and embolism, 640, mechanical heart-lung apparatus, Mechanical heart lung system, 684, for taking accurately timed arterial blood samples, Cerebral blood flow and metabolism in toxemias of pregnancy, 715
 Inter-American Congress of Surgery, Sixth, 128, 254, 382, 524
 International Society of Surgery, Thirteenth congress, 256, 384, 526
 Intestines, Cytologic diagnosis of cancer of descending colon and rectum, 24, Experimental mesenteric vascular occlusion, 393, Vesicointestinal fistulas, 411, Comparison of pain produced experimentally in lower esophagus, common bile duct, and upper small, with pain experienced by patients with diseases of biliary tract and pancreas, 573, anastomosis, Use of free peritoneal grafts in, 605
 Ischium, Posterior subsphincteric space, its relation to posterior horseshoe fistula, 222

JOINTS, Synovial osteochondromatosis, 457

Jones, John Paul, Death comes for admiral, 778

KIDNEY, function, Changes in renal function following ureteral transplantation, 299, Effect of reduced blood flow to liver in renal hypertension, 360, tuberculous, Transthoracic nephrectomy (right) for tuberculosis of, 599

Knee, Synovial osteochondromatosis, 457

LEG, amputation, Suction socket for above knee amputees, 335, Postphlebotic, results with femoral vein interruption, 541

Ligament, iliopectineal (Cooper's), Criteria, classification, and technique of, hernioplasty, 227
 Liver, studies, Morbid factors in experimental appendicitis, 165, function, Preoperative evaluation of, in patients with cirrhosis of, 357, Effect of reduced blood flow to, in renal hypertension, 360
 Lobectomy, Bronchiectasis, study of segmental distribution of pathologic lesions, 145
 Lobotomy, Unilateral prefrontal, for relief of intractable pain and termination of narcotic addiction, 385
 Lung, Bronchiectasis, study of segmental distribution of pathologic lesions, 145, Mechanical heart, system, 684
 Lymph node, dissection in cancer of extremities 591

MASTOIDECTOMY, Radical, anatomical considerations in surgical technique, 328
 Mediastinum, Intrathoracic goiter located in posterior, 57
 Medical art, Anatomical tabulae and initial letters in Vesalius' *Fabrica* and in imitative works, 96
 Medicine, history of, Anatomical tabulae and initial letters in Vesalius' *Fabrica* and in imitative works, 96
 Memoirs, Dr Irvin Abell, 646
 Menorrhagia, Observations on clotting mechanism in menstruation and, 764
 Menstruation, Observations on clotting mechanism in, and menorrhagia, 764
 Metabolism, Intravenous administration of combined fat emulsion into surgical patients, 398, Experimental ascites, effects of sodium chloride and protein, of dogs with constricted inferior vena cava, 529, Cerebral blood flow and, in toxemias of pregnancy, 715

NAIL, toe, Simplified treatment of ingrown, 638

Nailing, intramedullary, Effect of, on healing of fractures, experimental study, 609

Neck, Thyroglossal tract abnormalities—cysts and fistulas, report of 105 cases from the Johns Hopkins Hospital observed between the years 1926 and 1946, 727

Nephrectomy, Right transthoracic, for tuberculosis of kidney, 599

Nerves, vagus, Relief of pain in chronic (calcareous) pancreatitis by sympathectomy, 1, Vagovagal reflexes, electrocardiographic changes during vagotomy, 153, facial, Superficial lobectomy and total parotidectomy with preservation of, in treatment of parotid tumors, 237, splanchnic, Peptic ulcer following splanchicectomy, report of 13 cases, 271

Nitrogen equilibrium, Intravenous administration of combined fat emulsion into surgical patients, 398

Nutrition, Intravenous administration of combined fat emulsion into surgical patients, 398

OBSTETRICS, Outlet pelvimetry, results in measuring symphysis biparietal and sacral biparietal diameters in 145 primiparous women, 67, Physiological effects of cure, its failure to pass placental membrane or inhibit uterine contractions, 73, Rh factor, ed 362

Occlusion, Experimental mesenteric vascular, 393

Osteitis fibrosa cystica, Eradication of benign lytic bone tumors and immediate reconstructive surgery with emphasis on benign giant cell tumors, 735

Osteocartilaginous bodies, Synovial osteochondromatosis, 457

Osteochondromatosis, Synovial, 457

Ovary, Multiple primary cancer, study of 36 patients, 767

Oxygen, Some aspects of development of intrathoracic surgery, 629, Mechanical heart-lung system, 684, consumption, of brain, Cerebral blood flow and metabolism in toxemias of pregnancy, 715

December, 1949

CONTENTS—DECEMBER, 1949

COLLECTIVE REVIEWS

- Carcinoma of the Cervix, 1948 Survey of Its Treatment in the United States and Canada, RANDOLPH H HOGE, M D, F A C S, Richmond, Virginia 521
- Ovarian Tumors in Pregnancy HUGH G HAMILTON, M D, F A C S, and ROBERT S HIGGINS, M D, Kansas City, Missouri 525

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

Head

- Malignant Disease of the Face and Scalp Excision and Repair G M FITZGIBBON and D C BODENHAM 532

Eye

- Penicillin as a Prophylactic Against Ophthalmia Neonatorum A Comprehensive Study ARTHUR SACKS WILNER and EDWIN P SACKS WILNER 532
- Further Gonoscopic Studies on the Canal of Schlemm PETER C KRONFELD 532
- Vascularization of the Cornea Its Experimental Induction by Small Lesions and a New Theory of Its Pathogenesis DAVID G COGAN 532
- Pharmacology and Toxicology of the Cornea Contemporary Concepts KENNETH C SWAN 533
- Traumatic Choroiditis Review of the Literature and Report of 10 Cases PAUL TOWER 533
- Ocular Complications of Temporal Arteritis CARROLL SMITH and PHILLIP B GREENE 534

Ear

- Antibiotics in the Treatment of Diseases of the Ear, Nose, and Throat. A C FURSTENBERG 534
- Experiences with Penicillin in the Treatment of Acute Otitis Media N GREBELIUS and A SJOBERG 534
- Vestibular Function Prior to and Following Operation for Otosclerosis HELMER RASMUSSEN 535
- Biochemical Conditions in Patients with Otosclerosis. NIELS RISKAER 535
- Conditions of the External Auditory Meatus and the Tympanic Membrane in Patients with Otosclerosis SVEND SELSØ 535

Nose and Sinuses

- Carcinoma of the Antrum Report of 9 Cases, with a 10 Year Survey of the Literature CHARLES A SEELIG 535

- Diagnosis of Malignancy of the Nasopharynx Cytologic Studies by the Smear Technique LEWIS F MORRISON, EUGENE S HOFF, and ROSALIN WU 536

Neck

- The Treatment of Thyrotoxicosis I S RAVDIN, EDWARD ROSE, and JAMES D MAXWELL 536
- Amyloid Tumors of the Larynx, Trachea, or Bronchi A Report of 15 Cases DAVID B STARK and GORDON B NEW 538
- Anesthesia for Thyroid Surgery STANLEY ROWBOTHAM 601

SURGERY OF THE NERVOUS SYSTEM

- Brain and Its Coverings, Cranial Nerves 532
- Percutaneous Cerebral Angiography and Cerebral Abscess H F TABRITUS, A G FRØVIG, and K KRISTIANSEN 539
- Abscess of Brain Due to Clostridium Perfringens Treated with Penicillin RALPH B CLOWARD 539
- A Contribution to the Study of Chronic Subdural Hematoma G R HOFFMANN 539
- Multiple Brain Tumors HERBERT KRAUS 539
- Analysis of Electroencephalographic Findings in 40 Cases of Varied Brain Tumor Electroencephalographic Findings in Meningiomas HENRY M CUNEO, CARL W RAND, and H SJAARDEMA 540
- Operative Restoration Following Facial Paralysis OTTO LORENZ 540
- Spinal Cord and Its Coverings 535
- Intervertebral Disc Hernias of the Cervical Region J A LIÈVRE 541
- Peripheral Nerves 535
- Late Paralysis of the Ulnar Nerve and Occupational Accident. ALBERT MOUCHET and GUY SEILLÉ 541
- Traumatic Lesions of the Sciatic Nerve and Its Branches R FONTAINE, A DANY, and PH. SCHUMACHER 541

Miscellaneous

- Causalgic Syndromes W V MACFARLANE
 The Medical and Surgical Treatment of Hypertension F L REICHERT, V RICHARDS, E HOLMAN, A. L. BLOOMFIELD, and OTHERS
 The Role of the Nervous System as a Cause of the Immediate General Symptoms Following a Burn MARCELLO PEREZ

SURGERY OF THE THORAX**Chest Wall and Breast**

- Testosterone Propionate in the Treatment of Breast Cancer SIGVARD KAAE

Trachea, Lungs, and Pleura

- Surgical Extrapleural Pneumothorax in the Treatment of Large Tuberculous Cavities at the Upper Lobe of the Lung G L RONZONI
 Experimental and Clinical Study of Collapse Therapy with Fiberglas Wool and Fabric. THOMAS J C O'NEILL, HECTOR P REDONDO RAMIREZ, and ROBERT G TROUT
 An Evaluation of Extrapleural Pneumonolysis with Lucite Plombage JOSEIAH C TRENT, JAMES D MOODY, and JOSEPH S HIATT, JR
 The Malignant Nature of Bronchial Adenoma ALFRED GOLDMAN
 Pneumonectomy in a Case of Besnier Boeck's Sarcoidosis C L PETERSON
 The Clinical Use of a Prosthesis to Prevent Overdistention of the Remaining Lung Following Pneumonectomy JULIAN JOHNSON, CHARLES K KIRBY, C S LAZARIN, and J A COCKE
 Pyogenic Empyema with Extension Below the Diaphragm WILLIAM LEHMAN GUYTON and HOWARD W JONES, JR
 Contribution to the Study of Reports of Pulmonary Tuberculosis and Pregnancy E ROBECCHI and A BERNABO SILORATA
 Experimental Study of Fatal Pulmonary Embolism I URSO and G TROIA
 Tetanus Treated as a Respiratory Problem VERNON C TURNER and THOMAS C GALLOWAY
 Hemosiderosis of the Lung Due to Mitral Disease EUGENE P PENDERGRASS, EDWIN L LAME, and NORMAN OSTRUM
 Cavity Form of Pulmonary Neoplasm FRANK ISAAC and RICHARD E OTTOMAN

Heart and Pericardium

- The Surgical Treatment of the Patent Ductus Arteriosus P DECKER
 Surgical Treatment of Persistent Ductus Arteriosus DE VERNEJOUL and H MÉTRAS
 The Operative Handling of Aortic Coarctation FR. BERNHARD
 A Case of Aneurysm of the Aorta after Resection for Coarctation Cured by Excision J R BLICKMAN
 Probable Cyst of the Pericardium Associated with Disturbances of the Cardiac Rhythm ADRIANO ASCARELLI

Esophagus and Mediastinum

- 541 Surgical Treatment of Megadolichoesophagus Esophagostomy of Necessity or on Principle? JEAN PATEL and JEAN PAUL BINET 547
 542 Surgical Treatment of Carcinomas of the Distal Three Quarters of the Thoracic Esophagus and the Cardia. J F NUBOER 548
 607 A Case of Carcinosarcoma of the Esophagus ARTHUR PURDY STOUT, GEORGE H. HUMPHREYS, II, and LOUIS A. ROTTENBERG 549
 Thymectomy in the Treatment of Myasthenia Gravis 32 Cases L M EATON, O THERON CLAGETT, C ALLEN, and JOHN R. McDONALD 550

SURGERY OF THE ABDOMEN**Abdominal Wall and Peritoneum**

- Incidence of Hiatus Hernia and Associated Lesions Diagnosed with X-Rays IRVING B BRICK 551
 543 Revascularization Following Experimental Mesenteric Vascular Occlusion RUDOLF J NOER and JOHN WILLIAM DEER 551

Gastrointestinal Tract

- 543 A New Operation for Gastroptosis ANTON RAABE 551
 The Fate of Patients Following Stomach Operations FRITZ HEESE 552
 544 Regional Hypertrophic Enteritis at the Ileocecal Bottleneck (Crohn's Disease) G BROHÉE, L DAUMERIE, and G RYCKAERT 552
 The Development of Deep Duodenal Ulcer VICTOR HOFFMANN 552
 544 Treatment of Jejunal Ulcer A Comparative Follow-Up Study HENRY K RANSOM 553
 Concepts in Ulcerative Colitis A W MORROW 554
 544 Ulcerative Colitis Ileostomy Life E E DUNLOP 555
 Ulcerative Colitis Clinical Features, Diagnosis, and Treatment. GEOFFREY A PENINGTON 556
 575 Discussion on Hirschsprung's Disease T TWISTINGTON HIGGINS, F DOUGLAS STEPHENS, MARTIN BODIAN, and RICHARD MEYER 558
 597 Emetin and Appendicitis EDUARD MELCHIOR 559
 598 Volvulus of the Sigmoid Loop ALFREDO PIERINI 559
 Critical and Experimental Studies of Sutures of the Colon in Dogs D GEROTA, K PAMBUCCIAN, and F SCOBALU 559
 603 The Treatment of Carcinoma of the Rectum with Special Reference to the Preservation of the Sphincter Mechanism ROBERT MAILER 560
 Advantages of End To End Anastomoses with Separate Sutures in Surgery of the Gastrointestinal Tract A SAMAIN 560
 Continuous Suction Drainage JOHN R. PAINE 560
 545 Accuracy of Roentgen Diagnosis of Benign Gastric Ulcer C A STEVENSON and C W YATES 603
 546 Roentgenologic Studies of the Abdominal Aorta in Individuals over 50 Years of Age, as an Aid to the Differential Diagnosis Between Benign and Malignant Stomach Ulcers A ELKFLES 603
 546 Radiology of the Small Intestine in Old Age H J JUNGSMANN and L COSRY 606

Liver, Gall Bladder, Pancreas, and Spleen

- Use of Portacaval Anastomosis in Portal Cirrhosis
A C PATTERSON 560
- Primary Carcinoma of the Liver 25 Year Study
G F STRONG, H H PITTS, and J G MCPHREE 561
- Gall Bladder Tuberculosis GUSTAF ELFVING 561
- Gall Bladder Disease Among Filipinos, with a Report
on Ascariasis of the Biliary Tract F ESQUIVEL
and R I ALFONSO 561
- On Acute Pancreatic Affections Following Gastric
Resections for Ulcer or Cancer, and the Possi-
bilities of Avoiding them ERIK MILBOURN 562
- Indications and Results of Splenectomy WARREN
H COLE, LEROY WALTER, and LOUIS R
LIMARZI 562
- The Value of Splenectomy in Splenomegalies Caused
by Malaria KAZIM ISMAIL GÜRKAN and BÜLENT
TARCAN 564
- Combined Splenectomy and Portacaval Shunts in
Portal Hypertension LOUIS M ROUSSELOT 564
- Response of the Gall Bladder to Benassi Vitale's
Water Test in the Course of Cholecystography
After Gastric Resection ROSARIO CORSERI 604

Miscellaneous

- A Study of Penetrating War Wounds of the Abdomen
in the Finnish Fighting Forces During the War
of 1941-1944 E TIITINEN 565
- Massive Penicillin Therapy of Abdominal Actino-
mycosis GILMAN E SANFORD and RICHARD O
BARNES 566

GYNECOLOGY

- Carcinoma of the Cervix, 1948 Survey of Its Treat-
ment in the United States and Canada RAN-
DOLPH H HOGE, M D, F A C S, Richmond
Virginia 521

Uterus

- The Uterine Roentgenogram with Respect to Func-
tion, with the Exclusion of Malformations
E PHILIPP 567
- Clinical Classification of Carcinoma of the Endome-
trium ANDRÉS U RIESCO 567
- Reactions to X Ray and Radium Therapy in the
Treatment of Cancer of the Uterine Cervix
DANIEL G MORTON and JOHN A KERNER 606

Adnexal and Peruterine Conditions

- Remarks on the Pathologic Physiology of Endome-
trioses on the Occasion of 3 Observations of
Endometriosis of the Posterior Vaginal Vault
P MOCQUOT and R MUSSET 567
- Late Results of Revoltella's Anterior Hysteroendo-
ligamentopexy PIERO SPANIO 568

External Genitalia

- Bowen's Disease of the Vulva P BURCKE 568

Miscellaneous

- Culloscopy ALBERT DECKER 569

- The Effects of Various Estrogenic Preparations
Changes in the Vaginal Mucosa and General
Status of Climacteric Women Following the In-
jection of Aqueous Suspensions of Estrone and
Estradiol MILDRED VOGEL, THOMAS H Mc-
GAVACK, and JOSEPH MELLOW 569
- The Genitocolitic Syndrome CARLO VERCESI 570

OBSTETRICS

- Ovarian Tumors in Pregnancy HUGH G HAMILTON,
M D, F A C S, and ROBERT S HIGGINS, M D,
Kansas City, Missouri 525
- Pregnancy and Its Complications
- Diagnosis of Tubal Pregnancy A W SCHWENZER 571
- Diabetes Insipidus and Pregnancy P STRADELLA 571
- Puerperium and Its Complications
- Artificial Delivery and Morbidity in the Puerperium
R KELLER and L GIOANNI 571
- Delayed Hemorrhage Following Delivery Hemor-
rhagic Type of Puerperal Infection of Couve-laure
JEAN SNOECK and M ROCMANS 572
- Puerperal Scarlatina WILLI SCHULTZ 573

Miscellaneous

- Physiopathology of the Uterine Contraction JOSÉ
RAMÍREZ OLIVELLA 573
- Is the Hegar Sallheim Internal Pelvic Examination
Unnecessary? A MAYER 574
- Action of Folliculin and Progesterone on Water
Metabolism in Pregnancy TIMOTEO NOBILE 574
- The Action of Extracts of the Anterior and Posterior
Hypophysis on the Water Metabolism in Preg-
nancy TIMOTEO NOBILE 575
- Contribution to the Study of Reports of Pulmonary
Tuberculosis and Pregnancy E ROBECCI and
A BERNABÒ SILORATA 575
- Continuous Peridural and Caudal Analgesia in Ob-
stetrics JOHN G P CLELAND 601

GENITOURINARY SURGERY

- Adrenal, Kidney, and Ureter
- Hyperfunctioning Tumors of the Adrenal Cortex,
with a Report of 8 Cases WALTMAN WALTERS
and RANDALL G SPRAGUE 577
- Addisonian Crisis JOSEPH J KRISTAN 577
- Renal and Osseous Lesions J A LIÈVRE 579
- Consideration of Paraneoplastic Tumors HENRIQUE
MANOEL A RUPP 579
- The Problem of the Perirenal or Capsular Tumors of
the Kidney EWALD LEBBIN 581
- Tumors of the Renal Pelvis ALFRED GUETGEMANN 581
- The Roentgenologic Picture of Nonspecific Pyelitis
PAOLO BIONDETTI 604
- Bladder, Urethra, and Penis
- Biopsy and the End Results of Bladder Tumors A
FRANCISE 582

Radium Therapy in Carcinoma of the Female Urethra ROBERT E. FRICKE, and JAMES T. McMILLAN

605

Genital Organs

Retropubic Prostatectomy R. LICH, JR., O. GRANT, and J. E. MAURER

583

Varicocele. RAYMOND O. OLSON and ERIC P. STONE

583

Malignancy in Cryptorchidism WILLIAM A. CARROLL

584

On the Roentgen Aspect of Prostatic Atrophy NILS P. G. EDLING

604

Miscellaneous

Streptomycin in Urogenital Tuberculosis A. C. ABERNETHY and H. H. EDELBROCK

585

Urinary Tract Calculi J. C. KIMBROUGH and J. C. DENSLOW

585

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

Conditions of the Bones, Joints, Muscles, Tendons, Etc

Dyschondroplasia with Special Consideration of Its Unilateral Form (Ollier) HEINZ JUNGE

586

The Indications and Results of Management of Joint Tuberculosis PH. ERLACHER

586

Etiology of Congenital Dislocation of the Hip CARL E. BADGLEY

586

The Morphology of Congenital Coxa Vara KURT LINDEMANN

587

Congenital Dysplasia of the Hip Joint Relationship Between Congenital Subluxation and Congenital Dislocation VERNON L. HART

587

The Synovial Membrane of the Knee in Pathologic Conditions ROBERT SOEUR

588

Recent Advantages in the Roentgen Diagnosis of Pathologic Conditions of the Spine HENRIQUE BASILIO

605

Surgery of the Bones, Joints, Muscles, Tendons, Etc

Further Studies in Articular Replacement. STEPHEN S. HUDACK and J. WALLACE BLUNT, JR.

588

Arthroplasty of the Elbow joint A. VOGL

589

Tendon Transfers and Arthrodeses in Combined Median and Ulnar Nerve Paralysis J. WILLIAM LITTLER

589

Pinning for Slipping of the Epiphysis of the Femoral Head GUNNAR WIBERG

589

Open or Bloodless Treatment of Clubfeet ARNOLD SONNENSCHN

589

Operative Treatment of Clubfoot in Older Children and Adults HENRIK STRØM

590

Removal of the Base of the Proximal Phalanx in Hallux Rigidus ERIK SEVERIN

591

Fractures and Dislocations

The Importance of Intramedullary Nailing for the Treatment of Pseudarthrosis H. NUSSELT

591

The Late Results of Operative Treatment of Recurrent Dislocation of the Patella M. FELLÄNDER.

591

A Comparative Study of Methods of Treatment of Diaphyseal Fractures of the Leg GUSTAF ADOLF LANDOFF

59

Isolated Fracture of the Tarsal Scaphoid Final Result of Scaphoidectomy M. SOLERO

59

Orthopedics in General

Fundamental Concepts in the Treatment of Completely Arrested Volkmann Contracture PEDRO V. PEDEMONTE

59

A Contribution to the Question of the Origin of Anterior Paradiscal Defects and So Called Persisting Apophyses in the Vertebral Bodies ARVID HELLSTADIUS

593

SURGERY OF BLOOD AND LYMPH SYSTEMS

Blood Vessels

Observations on Raynaud's Disease, a Report of 35 Cases P. WERTHEIMER and R. GUILLET

591

Arterectomy for Arteritis Obliterans of the Lower Extremities LOUIS BAZY

591

Obstruction of the Superior Vena Cava. A Review of the Literature and a Report of 2 Cases FLOYD T. MCINTIRE and EDWIN M. SYKES, JR.

594

An Arteriographic Demonstration of Collaterals Between Internal and External Carotid Arteries F. MARK

605

Miscellaneous

Amputation for Gangrene Due to Occlusive Arterial Disease SAMUEL PERLOW and HAROLD A. ROTH

596

SURGICAL TECHNIQUE

Operative Surgery and Technique, Postoperative Treatment

Major Surgical Operations in the Presence of Bundle Branch Block PAUL H. PFEIFFER and JOHN S. LA DUE

597

Experimental Study of Fatal Pulmonary Embolism F. URSO and G. TROIA

COLLECTIVE REVIEWS

CARCINOMA OF THE CERVIX 1948 SURVEY OF ITS TREATMENT IN THE UNITED STATES AND CANADA

RANDOLPH H HOGE, M D, F A C S, Richmond, Virginia

MEDICINE, like other arts and sciences, is not static. It is forever in a state of flux, adapting scientific discoveries to its use, learning from experience, relying heavily on trial and error, maintaining the good, discarding the bad, and always on the lookout for something better. Seemingly established therapeutic procedures may become controversial, may be modified or discarded, or their superior worth may be substantiated. Sometimes the pendulum swings back and forth. And so, methods of therapy in one decade may or may not resemble those used in the preceding or subsequent decade. It is well for the informed physician to know the treatment most favored at a given time, and it is of interest and of possible value to predict what it will be next.

The first chosen treatment of carcinoma of the cervix in the era of modern medicine was radical surgery, as typified by the abdominal panhysterectomies introduced by Wertheim in the latter part of the nineteenth century. The discovery of radium in 1898 was to change this, for early in the twentieth century irradiation therapy was introduced (21) in the treatment of carcinoma of the cervix, and was to prove superior to the surgery of that time. For what seemed good and sufficient reasons, surgery was subsequently almost abandoned in favor of irradiation.

A review by Hoge (22) of the literature relating to the therapy of cancer of the cervix in the early

1930's supported this view because the great majority of the authors favored irradiation. Crossen had stated that the operation for carcinoma of the cervix was obsolete. Shaw (42, 43), one of England's most distinguished gynecologists and formerly a strong advocate of surgery, had published his advocacy of radium. Among those who had stated or implied that they preferred irradiation to surgery were Eymers, Laborde and Wickham, Dietel, Regaud (34, 35), Jansen, Schinz, Cutler (9, 10), Findley (15, 16), Pfahler, Doderlein and Voltz (48), Keene and Kimbrough, Burnam (4, 5), Simpson (44, 45), Lacassagne, Coutard, Healy (19, 20), Schmitz (39, 40), and Ward (49, 50). However, some writers expressed a preference for surgery in operable cases, among these were Bonney (1, 2) and Faure. Others favored a combination of surgery and irradiation. Among these were Reiprich, Duncan, Schlink and Chapman, Blakley (33), Gellhorn (17, 18), and others. For some time thereafter the trend toward irradiation in the treatment of carcinoma of the cervix seemed to continue. In 1937, Novak wrote, "The old question of surgery versus radium has been replaced by the question of whether there is now any place at all for radical surgery. The prevailing popularity of radiotherapy is fully justified by the fact that it gives final results just as good as those of even expert surgery."

Recently, however, the medical literature and forums show a reawakening of interest in the surgical treatment of this condition, an interest stimulated, no doubt, by recent advances in the

From the Department of Gynecology, Medical College of Virginia, Richmond, Virginia.

adjuncts to surgery which tend to decrease the morbidity and mortality in radical surgical procedures. Also, it has been discovered that the results of irradiation are far less than ideal.

Meigs, in 1939, (29) expressed satisfaction with the results of treatment of carcinoma of the cervix with x-rays and radium, but in 1945 (28) he stated that the Wertheim operation in properly selected cases may improve the results, and more recently he has found reason to add iliac lymphadenectomy by an extraperitoneal approach to irradiation in the treatment of certain cases (30). Taussig had previously introduced the method of adding transperitoneal iliac lymphadenectomy and bilateral salpingo-oophorectomy to irradiation in the treatment of stage II cases. Brunschwig, an advocate of the surgical treatment of carcinoma of the cervix, has reported the excision of all the pelvic viscera in a series of cases of advanced stages of this disease.

However, Buschke and Cantrell conclude that attainable improvement in irradiation therapy will save more patients than a return to surgery, and Carter and his associates (47), reporting on radical panhysterectomy and radical pelvic lymphadenectomy in selected cases, state that the majority of patients with carcinoma of the cervix will continue to be treated with accepted techniques of irradiation therapy.

SURVEY

With these thoughts in mind, it was decided that it would be certainly of interest and possibly of value to determine the present status of the treatment of carcinoma of the cervix in the United States and Canada. To this end, beginning in May of 1948, questionnaires were sent to the heads of the departments of gynecology, or of gynecology and obstetrics, in the accredited 4 year medical schools in the United States and Canada. There were 70 such schools in the United States and 9 in Canada. At the end of 1948, the time of this writing, all but 2 of the schools, that is, 77, or 97.5 per cent, had replied. An analysis of these replies now follows.

"ROUTINE" TREATMENT OF CARCINOMA OF THE CERVIX

Each school was asked to indicate if the "routine treatment of carcinoma of the cervix" was by irradiation alone, surgery alone, a combination of the two, or by some other method.

This statement was made without reference to the stage of the disease. The use of the word "routine" was unfortunate and is regretted. A few schools justly pointed out that no routine was

used but that each case was judged separately. A study of the answers shows that 48, or 62.3 per cent, of the schools in answering this section indicated that irradiation alone *without noted exceptions* was their method of treatment of carcinoma of the cervix. An additional 19 employed irradiation alone except in stage I, in stage I cases they used irradiation alone and other methods also. Seven more schools used irradiation alone except in stage I and II cases, in these stages irradiation alone or other methods also were used. One school reported exceptions in all stages to the use of irradiation alone. Two schools did not answer this section, but a study of their answers in the other sections in the questionnaire showed that one of them used irradiation alone except in alternate cases in stage I, and the other used irradiation alone except in stages I and II. In most of these instances in which exceptions were noted, irradiation was nevertheless the treatment in the majority of cases.

More accurate and detailed information is obtainable from the study of the treatment given according to the stages of the disease. This study is reported in subsequent paragraphs of this review.

STAGE CLASSIFICATION

As the stage of the disease may be regarded as an important factor in determining the type of treatment, it was decided to determine what classification of stages was used at each school.

Seventy-six schools answered this section. Fifty-seven, or 75 per cent, indicated that they used the League of Nations (27) classification exclusively, one school used both the League of Nations and the American College of Surgeons classifications. Eight, or 10.5 per cent, reported using the Schmitz (41) classification exclusively. Four schools used both the League of Nations and the Schmitz classifications. Six schools used other miscellaneous classifications. No school reported the use of the American College of Surgeons classification alone.

In an analysis of the foregoing it is seen that 82 per cent of the schools used the League of Nations classification exclusively or in combination with other classifications, and 16 per cent used the Schmitz classification exclusively or in combination with the League of Nations classification.

Having determined the classification of stages used by each school, the schools were questioned regarding the treatment used in each stage and were asked to indicate for each stage whether the treatment "in general" was irradiation alone, surgery alone, combined irradiation and surgery,

HOGE CARCINOMA OF THE CERVIX

or some other method. Here, the word "routine" was not used. The replies are analyzed in the following sections. In these sections, for the sake of uniform comparison, all stages reported are in terms of the League of Nations definitions (27), appropriate translations having been made in the returns to accomplish this.

STAGE I

Fifty-one schools, or 66 per cent, indicated irradiation alone as the treatment in general of stage I carcinoma of the cervix. Thirteen of these stated that in occasional selected cases surgery alone, or combined surgery and irradiation, is used. Fifteen schools, or 19.5 per cent, indicated only the combined method (irradiation and surgery) as the treatment in general. Two schools checked both surgery alone and the combined method as the treatment in general. Four schools checked both irradiation alone and the combined method as the treatment in general. Two schools indicated irradiation alone or surgery as the treatment in general. Two schools checked irradiation alone, surgery alone, and the combined method as the treatment in general.

A summary of the treatment of stage I carcinoma of the cervix shows that for the usual treatment irradiation alone was reported by 66 per cent of the schools, the combined treatment was reported by 19.5 per cent, and surgery alone was reported by one school. The remaining schools checked more than one method as the treatment in general, and all of these included irradiation among the methods. Of all the schools reporting, 27, or 35 per cent, indicated that surgery was used either alone or in combination with irradiation in some of the cases.

STAGE II

Sixty-two schools, or 80.5 per cent, indicated only the use of irradiation alone in the treatment of this stage. To these should be added 8 schools, which, though listing other methods also, indicated that, through preference or otherwise, the majority of stage II cases were treated by irradiation alone. This brings the total number of schools using irradiation alone in all or the majority of stage II cases to 70, or 90.9 per cent. Three schools indicated the use of the combined treatment only (irradiation and surgery) for stage II cases. To these should be added 4 schools which preferred the combined treatment in the majority of cases but sometimes used irradiation only. Thus, 7 schools, or 9.1 per cent, reported using the combined treatment exclusively, by preference, or in the majority of cases. No school

indicated surgery alone as its usual or preferred treatment in this stage. In brief, in this section the score was irradiation alone 90.9 per cent, combined irradiation and surgery 9.1 per cent, and surgery alone 0.

STAGE III

Seventy-three schools, or 94.8 per cent, reported only the use of irradiation alone as the treatment in stage III. The remaining 4 schools used irradiation alone as the usual method, but under some circumstances used other methods. One of these schools reported that it was at present studying "the results of irradiation plus regional lymphatic-bearing tissue excision." Another of these schools reported using the combined method or surgery alone in about 5 per cent of the cases. A third school stated, "if regression (after irradiation) is excellent it (the patient) may be subjected to surgery." The fourth school used combined irradiation and surgery as "second choice" to irradiation alone.

In short, 100 per cent of the schools reported the use of irradiation as the customary treatment in stage III, and 4, or 5.2 per cent, reported the additional use of surgery under some circumstances. One school reported the use of surgery alone in a small percentage of cases. No school gave the use of combined irradiation and operation or surgery alone as the usual treatment.

STAGE IV

All 77 schools indicated that irradiation alone was their treatment of stage IV carcinoma of the cervix. However, 3 schools, or 4 per cent, stated that although they used irradiation alone chiefly, sometimes they used combined irradiation and surgery. Two schools implied that, although irradiation was used if the patients were treated, some were not treated at all.

The type of irradiation was not asked for in connection with this section but 3 of the schools using irradiation alone indicated that only x-rays were used.

One of the schools, occasionally using combined irradiation and surgery, indicated that the surgery was "regional lymphatic-bearing tissue excision" and was used to study its value, another used the combined treatment as "second choice depending on involvement," and the third school occasionally used the actual cautery prior to the insertion of radium.

In brief, it is seen that all schools used irradiation as the treatment of stage IV carcinoma of the cervix, 3 schools indicated that sometimes some type of surgery was combined with irradiation

TABLE I—SUMMARY OF THE USUAL TREATMENT OF CARCINOMA OF THE CERVIX ACCORDING TO STAGES¹ BY 77 MEDICAL SCHOOLS IN THE UNITED STATES AND CANADA IN 1948

Usual method used	Percentage of schools			
	Stage I	Stage II	Stage III	Stage IV
Irradiation alone	66 ¹	90.9 ²	100 ²	100 ²
Combination alone	19.5	9.1	0	0
Surgery alone	1.3	0	0	0
Multiple methods	13			

¹League of Nations definitions.

²Exceptions were made as follows: stage I to irradiation alone 13 schools; stage II to irradiation alone 8 schools; stage II to combination alone, 4 schools; stage III to irradiation alone 4 schools; stage IV to irradiation alone 3 schools.

No school indicated the use of surgery alone in any stage IV case.

INTRAEPIDERMAL CARCINOMA

The statements in this review apply only to invasive carcinoma of the cervix. A separate section in the questionnaire dealt with the treatment of intraepithelial carcinoma (carcinoma *in situ*). It will be the subject of a separate report.

SUMMARY

1 The literature on the treatment of carcinoma of the cervix is partly reviewed.

2 The 79 accredited 4 year medical schools of the United States and Canada were polled regarding their treatment of this condition. Replies were received from 77 of them.

3 Eighty-two per cent of the schools used the League of Nations classification of stages exclusively (75%) or in combination with other classifications. Sixteen per cent used the Schmitz classification exclusively (10.5%) or in combination with other classifications. The League of Nations classification is used in this review.

4 In the usual treatment of stage I carcinoma of the cervix 66 per cent of the schools used irradiation alone, 19.5 per cent used the combined method (irradiation and surgery) alone, 1.3 per cent (1 school) used surgery alone, and 13 per cent listed multiple methods. In stage II the usual treatment was reported as follows: irradiation alone was used by 90.9 per cent of the schools, and the combination alone was used by 9.1 per cent. In stages III and IV irradiation alone was reported by all schools as the usual treatment.

5 Many notations were made by the schools indicating that exceptions to the usual method of treatment are made in some cases. Most of these exceptions were in the direction of surgery.

Factors present in individual cases which favor, or are believed to favor, surgery are early stages of the disease, a low degree of malignancy, evidence of radioresistance, and conditions which tend to make the patient a good operative risk.

CONCLUSIONS

Irradiation is still the most important and widely used method of treatment of carcinoma of the cervix in each and all of its stages. However, surgery is being used to an increasing extent in the early stages of the disease, especially in combination with irradiation. Surgery alone is little used except in highly selected early cases, or for study. Its use has been stimulated by improvement in the adjuncts to surgery.

OVARIAN TUMORS IN PREGNANCY

HUGH G HAMILTON, M D, F A C S, and ROBERT S HIGGINS, M D,
Kansas City, Missouri

THE first important reference to ovarian tumors in pregnancy was made by Ephraim McDowell on October 24, 1823 when he proved that the ovarian cyst can be removed with survival of the patient. The literature of the modern era of obstetrical surgery opens 23 years later in England, when Burd removed an ovarian tumor in a patient who was 3 months pregnant, the patient recovered but unfortunately aborted. Shortly thereafter, Marion Sims inadvertently removed a large ovarian tumor in a woman 3 months pregnant who went uneventfully to term and was delivered of a living child.

Since that incident the problem of ovarian tumors complicating pregnancy has frequently engaged the attention of medical authors, so that in 1903 and 1906 McKerron (63, 64) was able to collect 1920 cases from his own work and the literature. Among the cases with sufficient data for study, he observed a maternal mortality of 21 per cent for 720 cases, with a concomitant fetal mortality of over 50 per cent. However, few of his patients had early surgery, and he found that 25 per cent of the tumors lay in the pelvis and were undiagnosed until they obstructed labor. Heberg found that only 18 of 52 cases were diagnosed prior to laparotomy. McKerron's table (63) of the incidence of abortion for each month of gestation in the face of intervention follows:

Remy reported that 17 per cent of 321 patients aborted if they were not operated upon because of incarceration of the tumor or uterus in the pelvis, torsion of the tumor upon its pedicle, adhesions, pressure from the tumor mass, or because of infection.

The incidence of this complication is difficult of tabulation for the obvious reason that it is

TABLE I —INCIDENCE OF ABORTION

Month of gestation	Per cent of abortion
1	18.5
2	8.8
3	5.3
4	6.2
5	22.2
6	20.0
7	57.1
8	

frequently not diagnosed. Rosenthal observed 3 cases in 1400 pregnancies. McKerron quotes Flaischlen as seeing 5 in 17,832 pregnancies, Lohlein 2 in 1,300 pregnancies, and Tarnier 1 case in 1,738 pregnancies. Lynch observed the condition once in 500 cases, and in his article he stresses the importance of careful pelvic examination of the pregnant patient at her first visit to the office. Matthews had 12 cases in 8,500 deliveries, while Falls found 1 case per 650 pregnancies.

The size of the tumors varies widely in different reports, but for obvious reasons the later series show smaller tumors than the earlier ones. Miller and Willson, studying 934 ovarian tumors, found them to be small (under 5 cm) in 49.3 per cent, medium (5 cm to 10 cm) in 25.8 per cent, and large (over 10 cm) in 24.0 per cent. Of the small ones, 80 per cent resolved or ruptured spontaneously without surgery, so these authors concluded that the small tumors, unless hard in consistency, are simple, usually asymptomatic, and largely evanescent. In view of the luteal body changes, the same observation will be frequently made in carefully observed early cases of pregnancy.

The studies of various authors show a wide range of incidence of the different types of tumors

Goodall quotes Norris (68) and Spencer (99) as finding 68 per cent and 66 per cent, respectively, of their cases presenting cystomas and 23 per cent and 29 per cent, respectively, presenting dermoids. Conversely, he quotes Pfannenstiel as stating that dermoids and pseudomucinous cysts comprise the majority of ovarian tumors complicating pregnancy, and he cites the figures of Stuebler and Brandess as dermoids 58.3 per cent, pseudomucinous cysts 16.7 per cent, simple cystomas 16.7 per cent, and papillary cystomas 8.3 per cent. McKerron's (63) figures are simple and multilocular cysts 68 per cent, dermoid cysts 23 per cent, malignant neoplasms 5 per cent, and solid adenomas and fibromas 2 per cent.

As to the method to be employed in the care of ovarian tumors occurring in pregnancy, the literature becomes steadily more unanimous with the passage of time. The earliest case reports (McKerron, 63) show a high maternal and fetal mortality along with a high rate of interruption of pregnancy resulting from surgery. Flatau, in 1905, demonstrated abortion in 17.2 per cent of 284 patients subjected to surgery, whereas Berkeley and Bonney state that if surgery is adopted there is an abortion rate of 26.6 per cent and a gross fetal mortality of 33.3 per cent. They further contend that if surgery is not employed there is a gross fetal mortality of 21.6 per cent and an abortion rate of 12.5 per cent. Barrett, in 1913, studied the cases of 114 patients of whom 76 were subjected to surgery with 3 maternal deaths, and 64 of the surviving 73 carried their children to viability. Graefe said that from 14 to 20 per cent of the patients with ovarian tumors abort if untreated, as illustrated by McDonald's patient who went into premature labor at 7½ months of gestation and came to surgery 21 days later with a large dermoid cyst which had undergone torsion.

Early in the literature there appeared case reports of cysts in pregnancy drained by colpotomy, as in Gaudino's report of 10 cases, in which 3 patients were subjected to vaginal puncture. This procedure has been abandoned, and as early as 1920 Spencer (99) advocated the removal of the tumors as early as possible unless they occurred in the last trimester of pregnancy. The case reports of Litzenberg, Theron, Eiss, Caverly, Lynch, McCullough, Stein, H. T. Holmes, Ingraham (46, 47), Braddock, Mathieu and Holman, Massey and Helwig all show that early diagnosis of the condition and active treatment are essential to good results. The necessity of early diagnosis and active treatment, and the danger of temporizing are illustrated by the case of Davis, in which the patient was rehospitalized 1 week after dismissal

following a vaginal hysterotomy at 4 months, and required the resection of 25 cm of gangrenous ileum along with a gangrenous dermoid cyst measuring 12 by 16 cm. The patient survived only as a result of the technical surgical skill available.

The case report of R. W. Holmes is of interest as a scientific curiosity. He records the case of a patient upon whom he performed a cesarean section and a bilateral salpingectomy, in association with the removal of bilateral ovarian tumors, each described as the size of a grapefruit. Subsequently, this same patient was delivered of 2 other living children by cesarean section.

The later case reports of Trout and Kuder, Seibels, MacKenzie, Nucci, Capone, Moscoso, and Falk and Bunkin show that opinions generally favor the removal of any cyst large enough to be significant in the nonpregnant woman, as well as excision of all solid and all bilateral tumors. There is almost unanimous agreement that surgery should be performed prior to the last trimester of pregnancy, and if diagnosis is made in the last trimester that surgery should be done as an emergency measure in the event of torsion, compression, rupture, degeneration, or infection of the complicating tumor. If, in the late case, no surgical emergency demands intervention, the tumor should be removed at the time of cesarean section if there is obstruction by the tumor or if it is of such size or is so located as to make severe injury of the tumor probable at the time of vaginal delivery. If it appears that delivery can be performed vaginally with safety, arrangements should be made for excision of the tumor in the puerperium. This is necessary because more than 20 per cent of ovarian tumors undergo torsion in the puerperium.

In their studies of the hormone content of ovarian cysts removed during pregnancy, Watts and Adair usually, but not always, found gonadotropin, however, estrogen was by no means found constantly nor was it in high concentration when present. They rationalize this observation by the fact that the tumors (30) were removed early in pregnancy before the high estrogen levels were obtained.

In the past, ovarian surgery in pregnancy was approached with much trepidation because of the fear of abortion if the corpus luteum was disturbed. It now appears that the human female reacts differently to ablation of the corpus luteum in pregnancy than do experimental animals. Also, we may work with more freedom than formerly, because of our possession of potent endocrine preparations of corpus luteum extracts, or their

HAMILTON, HIGGINS OVARIAN TUMORS IN PREGNANCY

synthetic equivalents Pratt (84), in 1927, reported 2 patients in whom the corpus luteum was ablated in the first month of pregnancy and both patients went to full term and delivery. The following year, Oastler had the same result in a woman whose only remaining ovary was removed for torsion of a cyst at 7 weeks of gestation. Three years later Douglass recorded 3 similar occurrences, while Gardner cited the case of a woman from whom he removed at 6 weeks of gestation an ovarian cyst. This cyst was the size of a grapefruit and contained the corpus luteum, and a satisfactory outcome followed its removal. Hoenig and Warner attended a woman with only one ovary which they excised at 5 months of gestation because of a 10 cm cyst upon it. She, also, did not abort. Novak (71) states that the human female does not require the existence of a corpus luteum to carry her pregnancy to term, and Seegar and Delfs demonstrate that bilateral oophorectomy occasions no drop in the pregnandiol excretion of the pregnant human female. *Ergo*, pregnancy can be maintained by the gestin elaborated by the placenta. The most amazing case report is a later one by Pratt (85), in which he states that he performed an uterine suspension upon a sterile woman on the twenty-first day after the onset of her menstrual period and at operation removed the fresh corpus luteum for study. The patient missed the following menstrual period and went uneventfully to successful delivery at term. With the foregoing evidence before us and with the availability of pharmacologically potent progestin products, there is little excuse for failure to excise ovarian cysts in the first half of pregnancy, if we make the diagnosis of their presence.

The relationship of endometriosis to pregnancy has engaged the thoughts of many authors, and as early as 1930 Keene and Kimbrough showed that there is a sterility incidence of 40.9 per cent in patients with endometriosis. These authors urged conservative surgery, however, as they found that 28 per cent of the patients had subsequent pregnancies if their surgery was not radical. Scott states that the normal marital fertility rate is 88 per cent, which is contrasted to the sterility incidence as found by the following authors: Counsellor—32.1 per cent, Dreyfuss—35 per cent, Payne—40 per cent, Haydon—53 per cent, and Jenkinson and Brown—34 per cent.

With the high rate of infertility associated with endometriosis it is not remarkable that the literature contains so few case reports of endometriosis complicating pregnancy. In 1944, Scott was able to find but 7 cases reported, to which he added

his 2 cases. We find 17 cases at present, to which our series of cases adds 2, making a total of 19 cases. The following men have reported cases as listed: Sampson—1, Shaanning—1, Winestine—1, Lee—1, Aschheim—1, Novak (70)—3, Porter—1, von Franque—1, Wilson—1, McKenzie—1, Scott—2, and Pratt and Higgins—3. Aside from the discrete endometrial cysts which were removed because they were simply present as a tumor, there were others which gave symptoms from frank rupture or leakage due to their being markedly adherent with an attendant tug on their attachment by the upward growth of the pregnancy. Winestine noted the decidual reaction in the endometrial tissue of the tumor, which reaction was also commented upon by Novak (72). In both of our cases, the decidual reaction was quite pronounced in the tumor tissue.

Dermoid cysts are some of the most common tumors complicating pregnancy and unless they have been damaged by torsion, compression, or infection usually lend themselves to surgery without a great deal of technical difficulty. Again the importance of early surgery is obvious.

The bilateral dermoid cyst in pregnancy, however, offers features of unusual interest. Here, again, is a group of cases in which bilateral oophorectomy is practiced in pregnancy, and in which the studies of Andrews *et al*, Bowles (9, 10), and others show that the optimum time for surgery is early in the pregnancy, and that there are fewer abortions if the surgery is performed in the first 16 weeks of gestation. Andrews and Nicholls, in 1940, collected the cases of Campbell (16), Hoffmann, Waldstein, and many others to assemble 43 cases in the literature, to which they added their personal case of bilateral dermoid cysts in pregnancy. Since these 44 case reports were studied, there have appeared the writings of the following workers and their number of cases: King—1, Southward—1, Doyle and Daversa—1, Goodwin—1, Bowles (9, 10)—5, Ellis—1, Falk and Bunkin—2, and Berlind—1. These 13 cases added to the 44 cases previously reported make a total of 57 cases in the literature.

Waldstein operated upon his patient quite early, and then ran hormone assays throughout the remainder of the pregnancy. The values which he found did not vary from those in similar studies on normal pregnant women. It should be stressed that in the event the diagnosis of bilateral dermoid cysts is not made in time for early operation, elective cesarean section should be performed with simultaneous excision of the ovarian tumors.

We were able to find but 5 case reports of Brenner tumor associated with pregnancy. Siegel

removed a large Brenner tumor of the right ovary following closure of the uterine incision in a low cervical cesarean section with an uneventful convalescence. Novak (74) reported 3 cases, 1 was excised at 4 months' gestation with a good result, 1 was found in the hysterectomy specimen of a bilateral salpingo-oophorectomy and hysterectomy, and 1 was diagnosed by the decidual tissue found in the curettings of a patient subjected to laparotomy for a Brenner tumor. The fifth case was reported by Rogers who removed a 15 cm Brenner tumor at 12 weeks of gestation, followed by a normally continuing pregnancy and delivery.

Dysgerminoma in conjunction with pregnancy appears in the literature in 11 case reports. Schneider, von Szathmary (104), Schomaker, Dockerty, and Vesell each recorded 1 case of dysgerminoma removed early in pregnancy with a successful termination of the pregnancy at or near term. Nyst reports a case of dysgerminoma blocking the pelvis, which was removed at the time of cesarean section, and Stabler cites an identical case, as do Schneider and Vesell. Cunningham and McGrath were less fortunate in their case, their patient was given a cesarean section at term for dystocia from bilateral dysgerminomas which were simultaneously excised. She died of metastases 2 months postpartum. Abernathy's patient had a stillborn child when cesarean section was performed after 48 hours of labor for dystocia from obstruction by a dysgerminoma. The tumor was removed 3 months postpartum. Von Szathmary (104) also had a case in which the tumor was removed in the puerperium. Again, when surgical intervention occurred early, the complication was benign, but when the tumor was diagnosed and treated late the fetal and maternal mortality and morbidity rose.

As would be expected, there is a paucity of reports of the rarer tumors complicating pregnancy. Moore had a case in which a leiomyoma of the ovary was removed at 2½ months of gestation and the patient continued to delivery at term. This author was able to find 2 similar cases recorded, 1 by Brachetta-Brian and 1 by Olshausen. Brentnall's patient developed masculinization during the pregnancy, but her tumor obstructed the pelvis, so it was removed at the time of cesarean section. The patient's masculinization rapidly disappeared in the puerperium, but the baby was a hermaphrodite.

Bomze and Kirshbaum present the history of a 37 year old gravida-9 para-7 who had Meigs' syndrome complicated by toxemia of pregnancy. She aborted a dead fetus at 6 months of gestation, and was subjected to removal of a large solid tumor on

the third postpartum day. She died on the second postoperative day.

Spencer and Hollenbeck delivered a patient of a premature infant at 7 months of gestation and on the eleventh postpartum day removed a granulosa cell tumor measuring 22 by 17 by 11 cm. The authors' patient had a much smaller tumor (8 by 11 cm) which was removed at 16 weeks of gestation and the patient progressed uneventfully to term and delivered a healthy child normally.

In malignancy of the ovary complicating pregnancy one must again resort to the dictum that one cannot prove or disprove the malignancy of a lesion until it is subjected to microscopic study. Hence, one should subject the tumor to early surgery. Hagstrom found a patient with Krukenberg tumors which were operated upon at 5 months of gestation. Subsequently, the patient's condition deteriorated steadily and the pregnancy was terminated by a bag induction. The patient survived delivery for 6 hours. Campbell (15) cites a case in which a large ovarian carcinoma was removed with successful outcome of the pregnancy.

Bossert collected 14 cases of malignant ovarian neoplasms occurring in pregnancy, in addition to his personal case of bilateral serous papillary adenocarcinoma of the ovary at 10 weeks of gestation. His patient was subjected to bilateral salpingo-oophorectomy and hysterectomy with postoperative irradiation therapy and was alive and well when the report was written 3 months later. Of the 14 cases, 6 were sarcoma and 8 were carcinoma, with 4 maternal deaths due to malignancy, 4 cases were unreportable, and 6 patients were alive and well when last seen. Bossert refers to 39 cases of von Szathmary (105), of which 7 were sarcoma and 32 were carcinoma. Of the author's series, 3 cases showed malignant ovarian neoplasms, 2 of which were papillary cystadenocarcinomas operated upon at 14 weeks and 12 weeks of gestation with uneventful pregnancies and term deliveries, the third was a solid carcinoma of the left ovary discovered during labor and operated upon on the fifth postpartum day with death 8 months later from metastases.

CASE REPORTS

CASE 1 A 34 year old para-1 gravida-2, operated upon at 15 weeks of gestation with removal of a 10 cm dermoid cyst of the left ovary. There was delivery at term of a male child.

CASE 2 A 34 year old para-3 gravida-6, operated upon at 14 weeks of gestation with removal of a 7 cm luteal cyst of the left ovary. Delivery of a male child occurred at term.

CASE 3 A 30 year old para-0 gravida 1, operated upon at 12 weeks of gestation with removal of a 10

by 7 cm papillary cystadenocarcinoma on the left side, with no breaking through of the capsule. The right ovary was surgically absent. Delivery of a female child occurred at term. When examined 2 months ago, the patient was living and well, 18 months after operation.

CASE 4 A 19 year old para-0 gravida-1, operated upon at 8 weeks of gestation with removal of a 20 by 12 cm simple cyst on the right side. Delivery of a male child occurred at term.

CASE 5 A 22 year old para-0 gravida-1, operated upon at 13 weeks of gestation with removal of a partially gangrenous (due to torsion) 10 cm simple cyst on the right side. Delivery of a living female child occurred at 36 weeks of gestation.

CASE 6 A 28 year old para-2 gravida-3, operated upon at 16 weeks of gestation with removal of an 11 cm simple cyst of the left ovary. Delivery of a male child occurred at 35 weeks.

CASE 7 A 26 year old para-1 gravida-2, operated upon at 10 weeks of gestation with removal of a partially gangrenous (due to torsion) 6 cm dermoid cyst on the right side. Delivery of a female child occurred at term.

CASE 8 A 25 year old para-0 gravida-1, operated upon at 15 weeks of gestation with removal of a 7.5 cm dermoid cyst on the left side. Delivery of a male child occurred at 38 weeks.

CASE 9 A 33 year old para-1 gravida-2, operated upon at 14 weeks of gestation with removal of a 7 cm simple cyst on the right side with the corpus luteum of pregnancy in the specimen. Delivery of living, identical, female twins occurred at 38 weeks by cesarean section, because of a previous cesarean section for a true conjugate of 9.5 cm.

CASE 10 A 31 year old para-1 gravida-2, operated upon at 15 weeks of gestation with removal of a 6 cm dermoid cyst on the left side. Delivery of a female child occurred at term.

CASE 11 A 22 year old para-0 gravida-1, operated upon at 15 weeks of gestation with removal of an 8 cm endometrial cyst on the left side. The cyst was discrete, free of adhesions, and easily removed, upon microscopic study it showed a pronounced decidual reaction in the ectopic endometrium. Delivery of living female twins occurred at 37 weeks.

CASE 12 A 38 year old para-0 gravida-1, operated upon at 16 weeks of gestation with removal of an 8 by 11 cm granulosa cell tumor on the left side. Delivery of a male child occurred at term.

CASE 13 A 22 year old para-2 gravida-3, operated upon at 12 weeks of gestation with removal of a 6 cm parovarian cyst on the left side. Delivery of a female child occurred at term.

CASE 14 A 18 year old para-0 gravida-1, operated upon at 13 weeks of gestation with removal of a 7 cm simple cyst on the left side. Delivery of a male child occurred at term.

CASE 15 A 31 year old para-1 gravida-2, operated upon at 15 weeks of gestation with removal of a 6 cm simple cyst on the right side with the corpus luteum. Delivery of a male child occurred at term.

CASE 16 A 30 year old para-1 gravida-2, operated upon at 14 weeks of gestation with removal of a 5 by 6 cm papillary cystadenocarcinoma on the left side which had not broken through the capsule. Delivery of a female child occurred at term. This patient feels well and is in good health. Her tumor was removed 17 months ago and she is now 5 months pregnant again.

CASE 17 A 27 year old para-2 gravida-3, operated upon at 9 weeks of gestation with removal of a 7 cm luteal cyst on the right side. Inspection of the left ovary at the time of operation revealed that no corpus luteum was present. Delivery of a female child occurred at term.

CASE 18 A 37 year old para-5 gravida-8, operated upon at 39 weeks of gestation with removal of an 8 cm cyst which presented such marked dry gangrene that no histological details were discernible. Simultaneously, a living male child was delivered by low flap cesarean section and the patient had an uneventful convalescence.

CASE 19 A 29 year old para-1 gravida-2, operated upon at 34 weeks of gestation. Upon opening of the abdomen, the bloody contents of a ruptured endometrial cyst welled up through the peritoneal incision. The ruptured endometrioma was found to be adherent in the cul-de-sac, so living male twins were delivered by low flap cesarean section. Following closure of the uterine incision, the uterus was drawn up out of the wound and the ruptured endometrioma was excised from the cul-de-sac. The patient had a nonseptic postoperative course and was dismissed from the hospital on the twelfth postoperative day. The ectopic endometrium showed a pronounced decidual reaction.

CASE 20 A 26 year old para-0 gravida-1, operated upon at 14 weeks of gestation with removal of a 11 cm dermoid cyst on the right side. Delivery of a male child occurred at term.

CASE 21 A 28 year old para-1 gravida-2, operated upon on the fifth postpartum day with removal of an adherent left ovary about 6 cm in size and a normal right ovary. The left ovary was a solid carcinoma. The tumor was first observed as a palpable mass while the patient was in labor. Postoperative irradiation therapy was given but the patient died of metastases 8 months later.

The authors wish to thank Dr. Buford G. Hamilton for permission to observe 1 case which occurred while they were under his preceptorship. The author (H. G. H.) had the pleasure of surgically assisting Dr. Richard B. Schutz in another case which is included with his permission.

In the foregoing series of cases, gestation is calculated from the date of the first day of the last menstrual period. Interrupted, cotton (No. 30), mattress sutures were used on the peritoneum, interrupted, cotton (No. 30) sutures were used on the fascia, cotton (No. 50 or 30) ties were used in ligating abdominal wall bleeding vessels, and a

continuous cotton vertical mattress suture was used on the skin. In the suturing of viscera, Nos 0 and 00 chromic catgut sutures were used. The incision used was of the paramedian, rectus rolling type. Early ambulation was used. The patient sat up in bed on the first postoperative day, swung her feet off the bed on the second postoperative day, sat in a chair on the third day, and had bathroom privileges on the fourth day. If she developed gas pains she was mobilized earlier.

Intensive progestin therapy was instituted in all cases not terminated at surgery, the progestin being given at the rate of 10 mgm every 8 hours for 48 hours preoperatively and 72 hours postoperatively. The preparation used was proluton.

All operations were performed under spinal anesthesia, with either pontocaine or procaine, with light additional sodium pentothal (given intravenously) if the patient was nervous. There was no case of wound dehiscence, nor was there any case of incisional hernia.

Several cases of this series lend added weight to evidence presented earlier to the effect that the presence of the corpus luteum is not necessary for the human female to carry a child to term. Likewise, it is apparent that with good anesthesia and the liberal use of progestin therapy surgery of ovarian tumors complicating pregnancy can be undertaken in the first half of pregnancy with relative impunity. It is probable that one of the main reasons for the greater success of early surgery, as compared with surgery later in gestation, is the fact that with a smaller uterus it is technically and mechanically easier to excise the tumor with a minimum of handling of, and trauma to, the uterus. Of paramount importance is the early examination of patients, the diagnosis of the pelvic pathology, and immediate surgical intervention.

CONCLUSIONS

1 All pregnant women should be encouraged to report for examination during the first 75 days of their pregnancy.

2 A careful searching bimanual examination should be made of every pregnant woman on her first visit to her obstetrician.

3 The same ovarian tumors that would warrant surgical intervention in the nonpregnant woman, demand surgical intervention in the pregnant woman.

4 The safest time for operation is in the first half of pregnancy.

5 If a surgical emergency arises, ovarian tumor surgery should be undertaken at any period of gestation.

6 If any ovarian tumor that makes for dystocia escapes early diagnosis and care, it should be removed at the time of elective cesarean section.

7 Adequate progestin therapy is a useful adjunct to ovarian tumor surgery in pregnancy.

8 The greater the amount of time elapsing between surgery and labor, the firmer the wound will be.

9 Two additional cases of endometriosis complicating pregnancy are added to the literature, making a total of 19 cases.

10 Three cases of malignant ovarian neoplasms complicating pregnancy are added to the literature.

SURGERY OF THE HEAD AND NECK

HEAD

Malignant Disease of the Face and Scalp: Excision and Repair G M FITZGIBBON and D C BODEN
HAM *Brit J Plast Surg*, 1949, 2 13

Malignant disease of the face and scalp should be treated by a co operative program outlined by the radiotherapist, the general surgeon, and the plastic surgeon. The surgeon, taking advantage of the developments in anesthesia and blood transfusion techniques, should extend the field of operability. The plastic surgeon can complete the closure of any large defect.

Excision of epitheliomatous or rodent ulcers is undertaken when a case is considered unsuitable for radiation because of the site, when recurrence after heavy irradiation has occurred and further radiation would produce necrosis, when necrosis of bone or cartilage is present as a result of radiation, and recurrence may or may not be present, and when necrosis and sepsis are present and further radiation seems inadvisable.

In all cases certain general principles are followed. To prevent possible recurrence, wide and often ruthless excision is done with a cold knife and not diathermy. All doubtful tissue is sacrificed. Biopsies taken from one part of the lesion are not representative of the whole. At times large areas of the skull must be removed and the dura is exposed. Heavily irradiated tissues with signs of necrosis should be removed. When glands are palpable, a full block dissection of the side of the neck should be done. Occasionally it is wise to ligate the external carotid artery in neck dissections to prevent troublesome hemorrhage.

Immediate cover should be provided to decrease the possibility of sepsis, scarring, and deformity. Free, thick skin grafts may be used if a suitable base remains after excision. Usually, large flaps are preferable when the bed is irregular or the dura or other important structures are uncovered. The secondary defects of face and scalp lend themselves readily to skin grafts.

Illustrative case records with photographs are presented to demonstrate the application of these principles.

Closed circuit anesthesia by endotracheal tube, preventing loss of fluid and heat and giving the necessary free access for surgical procedures, is used. Blood transfusion at the commencement of the operation, and continued during and after surgery, is used, and elderly patients are found to tolerate lengthy procedures well. Late repair is done after a substantial period if it is believed to be necessary.

EYE

Penicillin as a Prophylactic Against Ophthalmia Neonatorum: A Comprehensive Study ARTHUR SACKS-WILNER and ERWIN P SACKS-WILNER *Arch Ophthalm*, Chic, 1949, 41 444

The efficacy of penicillin in the prophylaxis of ophthalmia neonatorum was studied in 251 newborn infants. Immediately after birth a conjunctival smear was taken from each eye and a penicillin solution containing 5,000 units per cubic centimeter was instilled into each conjunctival sac. Smears were made 24 hours later, and upon discharge from the hospital.

At birth, 37 infants showed pus cells, 52 had gram positive cocci, 1 had gram positive rods, and 2 had gram negative rods. Twenty-four hours after birth 20 infants showed pus cells, 25 had gram positive cocci, 1 infant had gram positive rods, and 1 had gram negative rods. On discharge from the hospital, 11 infants had pus cells in the smear without evidence of infection, 32 had gram positive cocci, none had gram positive rods, gram negative cocci, or rods.

It is concluded that local instillation of penicillin in the newborn is nonirritating, painless, prophylactic, and therapeutic. FRANK W NEWELL, M D

Further Gonioscopic Studies on the Canal of Schlemm PETER C KRONFELD *Arch Ophthalm*, Chic, 1949, 41 393

Under normal conditions of life, the canal of Schlemm contains a colorless fluid. Various experimental procedures cause gonioscopically visible entrance of blood into the canal. When the process is fully developed a continuous, homogenous salmon red or brick red band is visible in the pigment ring of the trabecular zone. The condition is produced by sudden drops of intraocular pressure, or by raising the venous pressure. The blood may be displaced out of the canal with ease—by compression of the globe, if the condition was produced by ocular hypotonia, or by release of compression if produced by an increase in venous pressure. These observations lend support to the concept that a pressure gradient and, consequently, a continuous flow exists between the canal and the anterior scleral vein.

Vascularization of the Cornea: Its Experimental Induction by Small Lesions and a New Theory of Its Pathogenesis DAVID G COGAN *Arch Ophthalm*, Chic, 1949, 41 406

New blood vessel formation in the rabbit cornea was induced by small, discrete lesions produced with actual cautery or by local injection into the corner of

SURGERY OF THE HEAD AND NECK

0.1 normal hydrochloric acid or sodium hydroxide. A latent period of approximately 2 days was followed by engorgement of proximal vessels, chiefly the venules and capillaries, and by the formation of saccular aneurysms on their walls. These aneurysms burst, causing hemorrhage into the corneal stroma and prompt deflation of the vessel. The hemorrhagic area then became riddled with new capillaries, most of which receded in the course of a few days, leaving a few loops directed toward the lesion.

That the hemorrhagic extravasates played a determinant role in this new blood vessel formation was disproved by the absence of similar phenomena occurring when blood was injected into the cornea. That toxins played a significant part seemed unlikely, since no abnormal "permeability factor" could be demonstrated in extracts from corneas that were undergoing vascularization. The one event which appeared to be correlated with, or to precede, the vascular changes was swelling of the corneal stroma. The thesis is therefore presented that the engorgement of the vessels, the formation and ultimate bursting of the saccular aneurysms, and other events leading to interstitial vascularization of the cornea are due to reduction in the tissue compactness of the cornea in the region of pre existing vessels.

FRANK W. NEWELL, M.D.

Pharmacology and Toxicology of the Cornea. Con-temporary Concepts. KENNETH C. SWAN. Arch Ophth, Chic, 1949, 41 253

The author states that the precorneal film contains protein and mucoprotein and this layer has high wetting properties. The viscosity is maintained by a balance in the rate of evaporation and the lacrimal secretion.

Pathological changes occur in the cornea when the precorneal film undergoes changes, and keratitis results. Apparently, there is a hormonal control of lacrimation, as indicated in keratoconjunctivitis sicca during the menopause. Keratoconjunctivitis sicca may also follow chronic conjunctivitis with secondary inflammation of the lacrimal ducts. Methyl cellulose (a 0.5 to 1.0 per cent solution of 4,000 centipoise type of methyl cellulose containing 0.9 per cent of sodium chloride) has appeared to be the best type of artificial tear.

The corneal epithelium is sensitive to injury and nutritional disturbances. It has a high metabolic rate and heals quickly. Local anesthetics seem to impede epithelial repair, while a bandaged eye results in more rapid healing of the epithelium.

The effect obtained from local anesthetics depends upon physical properties. In general, a highly surfacel active compound penetrates well, has a greater faced active compound wetting power miscibility, and a greater irritating factors to be considered in relation to the cornea. (1) the physical properties of a drug vehicle, (2) the pH of the drug solution (usually pH 6-8 is well tolerated), (3) surface activity—dilute wetting agents are preferable, and (4) vehicles with emollients are desirable.

Knowledge of the characteristics of permeability of the cornea is important and this knowledge aids in treating bedewing of the cornea, which occurs in acute congestive glaucoma. The use of glycerin clears the cornea for a period of time.

Bowman's membrane and the corneal stroma have a low metabolic activity. Bowman's membrane is more permeable than the epithelium.

Prompt treatment of acid and alkali burns is important and prolonged irrigation with isotonic sodium chloride is necessary.

The removal of a rust ring involving the corneal stroma is one of clinical judgment. It may be removed, or the surgeon may wait for the lesion to heal over, and if too much reaction occurs it may be removed at that time.

In deep corneal lacerations, silver proteinate produces an opacity in Descemet's membrane.

The endothelium is very sensitive to physical and chemical injury, which is followed by edema of the overlying stroma, consequently great care in selecting an irrigating solution for the anterior chamber is essential.

A better clinical effect is obtained from drugs which enter the anterior chamber through the cornea by having the drug contact a larger portion of the cornea and remain in contact with it for a greater length of time. Vehicles of high viscosity and miscibility aid in this effect too.

Drugs which are highly water-soluble should be administered in an oil vehicle and drugs which are highly oil-soluble should be given in an aqueous vehicle.

Iontophoresis is a method by which a greater concentration of drug can be obtained in the cornea or anterior chamber. J. WOODHULL OVERTON, M.D.

Traumatic Choroiditis. Review of the Literature and Report of 10 Cases. PAUL TOWER. Arch Ophth, Chic, 1949, 41 341

The author makes a differentiation in ruptures of the choroid. One type of rupture is direct and the trauma is at the place of impact, another type is indirect and the trauma is produced by contrecoup.

The second type, which occurs in the posterior segment, is more common. In the present article the author deals with the indirect type.

The lesion may occur singly, or multiple breaks may occur in the choroid, near the optic papilla. These breaks are usually segments of a circle in shape, and follow the outline of the disc in a concentric fashion or extend parallel with the equator.

There are many theories as to the cause of this condition. Most of the theories involve vascular changes, either rupture of vessels, vasoconstriction, or pulling of the vessels by the optic nerve when the injury occurs. Other theories favor some nerve control mechanism. All agree there is tissue necrosis, Many smaller vessels of the choroid disappear, atrophic proliferation of neuroglia, wandering pigment, and new vessels were observed. Scar tissue

formation was present in the inner layer of the sclera.

Ten cases are presented. The choroidal lesions are of various shapes, sizes, and positions. Two of the patients had almost normal vision. In all cases, necrosis and atrophy of the choroid were present. The author believes that the term "rupture of the choroid," as it is usually applied to the discontinuity of the choroid following nonpenetrating injury, is a poor one and that traumatic choroiditis would be more appropriate. Furthermore, he believes arciform traumatic choroiditis should be reserved for the concentric lesions and that all other lesions of irregular outline should be described as diffuse traumatic choroiditis. J. WOODHULL OVERTON, M.D.

Ocular Complications of Temporal Arteritis. CARROLL SMITH and PHILLIP B. GREENE. *Am J Ophth*, 1949, 32: 685.

The original description of temporal arteritis came from the Mayo Clinic in 1932. Since then more than 40 cases have been reported, and about half of them have been associated with visual disturbance.

The authors record the details of 4 additional cases with this complicating feature. The diagnosis is suggested when elderly individuals with advanced arteriosclerosis recall having felt nodules along the temples and severe head and scalp pains some weeks before the occurrence of eye symptoms. The marked visual loss, which may eventuate into total blindness, is associated with a comparative lack of fundus findings. The interruption of blood flow probably comes on gradually so that the dramatic changes of ischemic edema and cherry-red spot do not occur. In cases with visual disturbance it is likely that the ophthalmic artery is involved. Certainly the affection is more widespread than the term, temporal arteritis, would indicate. In all the cases reported the temporal arteries were hard, nodular, and without pulsation. Section was bloodless and showed an obliterative endarteritis with marked cellular infiltration of the muscular coat.

EAR

Antibiotics in the Treatment of Diseases of the Ear, Nose, and Throat. A. C. FURSTENBERG. *Ann Otol Rhinol*, 1949, 58: 5.

There can be no criticism of the immediate administration of penicillin in cases in which the diagnosis of acute infection is made. When response to the drug is unsatisfactory, the organism must be identified and its sensitivity determined. The use of another antibiotic may be indicated.

To be effective, penicillin must come in actual and sustained contact with the organism, therefore, topical administration of penicillin and penicillin aerosols are of little or no value. A dense capsule surrounding a chronic abscess in the neck is a barrier to penicillin therapy. Penicillin does not cure chronic suppurative otitis media and mastoiditis, osteo-

myelitis of the calvarium and facial bones, or chronic sinus disease. Operative procedures are imperative in such cases if one hopes to obtain a cure.

The ability of aureomycin and chloromycetin to permeate cell membranes, and the blood-brain barrier makes them agents of great promise.

Streptomycin is effective in tuberculous adenitis and in tuberculous lesions of the mucous membrane. Dihydrostreptomycin, which is comparatively free from neurotoxic effects, will soon replace streptomycin in the treatment of these conditions.

JOHN R. LINDEN, M.D.

Experiences with Penicillin in the Treatment of Acute Otitis Media. N. GREFFELIUS and A. SJOBERG. *J. Lar. Otol*, Lond., 1949, 63: 286.

The authors have reviewed the results of penicillin therapy in 366 consecutive cases of acute otitis media during the year of 1948, as compared to a clinical control group of 329 patients in 1947 who were treated prior to the introduction of penicillin in Sweden.

The bacteriological findings from the external auditory canal in patients treated in 1948 revealed the predominant organisms to be hemolytic streptococci and staphylococcus aureus, 91.6 per cent of the patients in whom bacteria was present proved to be sensitive to penicillin in vitro.

The penicillin dosage varied from 15,000 units (3 injections in 24 hours) for infants up to 100,000 units (3 times daily) for adults. The average dose per patient was 1,500,000 units given in an average of 8.6 days. The penicillin therapy was stopped in the simple cases after the ear had been dry for 2 or 3 days, unless the state of the tympanic membrane or some other circumstance called for longer treatment. No certain allergic manifestations were observed except in 2 cases of suspected "drug fever."

The principal findings in the penicillin-treated series and in the control series were as follows:

1. Penicillin treatment, started as early as possible and given prophylactically to prevent complications, considerably shortens the period of hospitalization.

2. The average duration of hospitalization for patients who were not treated with sulfonamides was 20 days, for patients who received sulfonamides 14.6 days, and for those treated with penicillin, 11.9 days.

3. The average duration of secretion in cases in which penicillin was used was 8 days, in comparison with 12.7 days in the sulfonamide-treated group, and 15.9 days in the group treated without the use of sulfonamides.

4. During penicillin treatment the sedimentation rate shows an average decrease of 32.2 mm. during the first week of treatment, compared to a decrease of 6.8 mm. in the control group.

5. Only 9 of the 366 patients whose cases were studied (2.6%) required operation. The percentage is practically the same as that found in 2,113 out-patient cases of acute otitis media in the same 11 fi-

SURGERY OF THE HEAD AND NECK

tution where the operative percentage was 25 per cent. This was compared to an average of 8 to 20 per cent of operations for mastoidectomy among cases of acute otitis media during the years from 1938 to 1947 in the outpatient clinic.

In addition, the authors mentioned 6 cases with obvious signs of mastoiditis in patients who were treated with penicillin and in whom healing resulted without surgical intervention. In 6 cases of meningitis, intramuscular injections of penicillin were necessarily supplemented with intrathecal administration of penicillin to bring the meningitis under control.

EUGENE L. DERLACKI, M D

Vestibular Function Prior to and Following Operation for Otosclerosis

HELMER RASMUSSEN Arch Otolaryngol, Chic, 1949, 49 402

The author presents the results of his investigations of vestibular function in 79 of 88 patients operated upon for otosclerosis according to Popper's method at the Sundby Hospital, Copenhagen.

In 27 per cent of 67 patients questioned, vertigo was present preoperatively. In 16 per cent of the 79 patients it was present for 1 to 15 months postoperatively.

Spontaneous nystagmus occurred following the operation in all but 4 of the patients. Various tests for fistula were performed, and the results appear in Table I below.

The author concludes that if the fistula has not closed after a period of 6 months, the chance of its remaining open is great.

Labyrinthine function also was investigated by rotation tests. Examinations with the head in the upright position revealed preoperative vestibular abnormalities in 7 cases. Postoperative findings suggested a reduced function of the lateral horizontal canal on the side of operation, but in only 2 cases was the reduced function permanent.

Rotation with the head bent forward or backward suggested that there were disturbances of function of either the superior or the posterior canal, or both, postoperatively in 12 patients. The abnormality persisted in only one case.

Rotation with the head bent to the right or to the left gave inconclusive results.

Caloric tests were made before operation with the use of 100 c c of water at 10 to 15 degrees C. Five patients reacted abnormally to this test. Postoperatively

tively, the caloric test was made by the insufflation of air and with the head in various positions. The test revealed various degrees of abnormality in 48 of 76 patients. In 6 of the 48 patients no caloric reaction was obtainable although the author notes that in 5 of the 6 patients spontaneous nystagmus was present.

JOHN J. BALLENGER, M D

Biochemical Conditions in Patients with Otosclerosis

NIELS RISKAER Arch Otolaryngol, Chic, 1949, 49 414

The author has examined fasting blood serum from 51 patients who had been operated upon for otosclerosis in 1947. Analyses were made for calcium, inorganic phosphate, phosphatase, total cholesterol, albumin, and globulin.

In general, it may be said that in the great majority of cases of otosclerosis, normal values were found on the first analysis for all the examined substances. Where slight deviations from normal were found, control analyses revealed normal levels in all cases. The author believed he would have found more abnormal values if stricter normal limits had been observed, as has been done by other authors. He also comments that differing reports by other surgeons "may denote variations in the serum concentration in different phases, active and inactive, within the course of otosclerosis." He doubts such a theory.

JOHN J. BALLENGER, M D

Conditions of the External Auditory Meatus and the Tympanic Membrane in Patients with Otosclerosis

SVEND SELSØ Arch Otolaryngol, Chic, 1949, 49 420

In examining patients in the ear department of Sundby Hospital, Copenhagen, the author has tried to discover conditions in the external auditory meatus and the tympanic membrane which might be of importance in differentiating between otosclerosis and other forms of deafness.

In the present study, 29 otosclerotic patients and 29 control patients who had no ear disease were used. Tests were made for sensitivity of the skin and variation in the lumen of the external meatus, for Schwartze's sign, and for cerumen production.

The conclusion reached by the author was that "the external auditory meatus and the tympanic membrane present no characteristics that may contribute to differentiate otosclerosis from other forms of deafness."

JOHN J. BALLENGER, M D

NOSE AND SINUSES

Carcinoma of the Antrum Report of 9 Cases, with a 10 Year Survey of the Literature

CHARLES A. SEELIG Ann Otol Rhinol, 1949, 58 168

Nine cases of carcinoma of the antrum are presented. Only one patient survived. This patient was treated by radical antrotomy, and is living and free of recurrence 7 years after operation.

The signs and symptoms which should suggest antral carcinoma are unilateral nasal discharge, nasal

TABLE I — FISTULA SIGN AFTER OPERATION

Number of months after operation	Patients in whom sign was still present	Patients in whom sign later disappeared	Total
1, to 1½	8	5	20
1½ to 2	7	5	20
2 to 6	13	1	17

Total	46	11	57

INTERNATIONAL ABSTRACTS OF SURGERY

obstruction, epistaxis, ulceration of the hard palate, anesthesia of the face, lacrimation, pain, swelling exophthalmos, and diplopia. The prognosis is poor even when surgery is combined with radiation therapy. The average length of life in the reported cases was 57 months from the date of diagnosis. Early diagnosis and radical therapy are essential to success.

JOHN R. LINDSAY, M.D.

Diagnosis of Malignancy of the Nasopharynx Cytologic Studies by the Smear Technique LEWIS F. MORRISON, EUGENE S. HOPP, and ROSALIN WU
Ann Otol Rhinol, 1949, 58, 18

The diagnosis of exfoliating carcinoma of the nasopharynx can be made by examining the secretions for malignant cells by the Papanicolaou technique. The examination should be used as an adjunct and not as a substitute for biopsy. Positive smears were obtained in 7 of 8 proved cases of nasopharyngeal carcinoma. In one instance the persistence of a positive smear encouraged the authors to take repeated biopsies, and the fifth biopsy showed anaplastic carcinoma. The method is time-consuming and requires meticulous attention to detail.

JOHN R. LINDSAY, M.D.

NECK

The Treatment of Thyrotoxicosis I. S. RAVDIN, EDWARD ROSE, and JAMES D. MAXWELL *J Am Med Ass*, 1949, 140, 141

With the possible exception of the true toxic adenoma, it seems probable that the primary cause of thyrotoxicosis lies outside the thyroid gland itself. Certain clinical evidence suggests the possible etiologic importance of functional disturbances in the higher psychic centers, the hypothalamus, the anterior pituitary, the autonomic nervous system, the gonads, and the adrenals. Proof of such relationship, however, is still lacking. Theoretically, the thyrotoxic state might be considered therapeutically vulnerable at three possible levels: (1) by an attack on the initiating factors, (2) at the thyroid itself, or (3) at the level of the peripheral target tissue cell where the impact of the excessive output of thyroid hormone is exerted. The principal approach at present is at the thyroid level.

Those methods of treatment which require consideration may be listed as follows: (1) iodine therapy, (2) treatment with goitrogenic compounds, (3) external irradiation of the thyroid or pituitary, (4) radioactive iodine therapy, and (5) radical resection of the thyroid gland.

Iodine in any absorbable form will produce a variable degree of remission in at least 95 per cent of thyrotoxic patients. The use of iodine should, in general, be limited to (1) preoperative preparation, (2) treatment of the "thyroid storm," (3) temporary postoperative administration, (4) occasionally as a therapeutic test when the diagnosis of thyrotoxicosis is in doubt, and (5) certain cases of hyperophthalmopathic (Graves' disease).

The goitrogenic compounds now being used produce a remission in the thyrotoxic state by inhibiting the synthesis of thyroid hormone. Although their administration alleviates the symptoms of toxicity, the glands of patients receiving these drugs remain hyperplastic and show the typical histologic features found in untreated thyrotoxic patients. Patients with large or nodular goiters, or those recently treated with iodine may be slow to respond. Some patients are partially or completely refractory without apparent reason. The present consensus indicates that sustained remissions following prolonged therapy cannot be expected in more than about 50 per cent of cases. The authors' experience suggests that the majority of patients showing a sustained remission and a return to normal activities have exhibited the milder forms of thyrotoxicosis, with minimal goiter, slight to moderate elevation of basal metabolic rate, and no cardiac or other visceral complications.

These goitrogenic substances have proved useful in the prolonged control of certain thyrotoxic patients in whom thyroidectomy cannot, for various reasons, be undertaken even though, theoretically, it is the treatment of choice. This group includes certain older patients, those who refuse operation, and those who cannot be brought by medical therapy to a point at which operation can be considered justifiably safe.

Although most patients can be satisfactorily prepared for thyroidectomy by the use of iodine, it has proved inadequate in two important groups of cases: (1) certain severely toxic patients in whom iodine alone fails to produce a satisfactory preoperative remission, and (2) patients rendered "iodine fast" by the prolonged use of this substance. In such patients a complete remission can usually be produced by the prolonged use of goitrogenic agents.

Irradiation of the pituitary has received a limited trial. Its usefulness at present would appear to be restricted to certain patients with the hyperophthalmopathic syndrome of toxic diffuse goiter (Graves' disease). In these patients thyrotoxic phenomena are frequently mild and may be at times entirely absent or replaced by evidence of hypothyroidism. Ocular signs and symptoms dominate the clinical picture and may include varying degrees of proptosis, periorbital and palpebral edema and pigmentation, edema and congestion of the conjunctiva, keratitis, lacrimation and swelling of the lacrimal glands, fixation of the eyeball, pseudo hypertrophy of the extraocular muscles, papilledema or optic neuritis, and edema or infiltration of the orbital tissues. This ophthalmopathic syndrome occasionally develops rapidly and unexpectedly after thyroidectomy in patients with minimal preoperative ocular signs, but its presence can usually be suspected by one or more of the aforementioned manifestations. Too great a suppression of thyroid function in such cases, whether by thyroidectomy or

SURGERY OF THE HEAD AND NECK

any other means, may be followed by disastrous progression of the ocular changes. The pathogenic mechanism of these changes is still obscure, but some kind of abnormal effect is believed to be exerted by the anterior pituitary on the extraocular muscles and the orbital tissues. Suppression of thyroid function appears to aggravate the ocular disturbance by removing an inhibitory effect on the anterior pituitary. In the presence of pronounced ocular symptoms and a mild thyrotoxic state, thyroidectomy is, in the authors' opinion, contraindicated. Therapy should be aimed at inhibition of anterior pituitary activity and has included such measures as desiccated thyroid, estrogenic substances, and the intermittent use of iodine. Irradiation of the pituitary, while far from being precisely controllable in its placement, or in the exact amount delivered to the pituitary, nevertheless appears justifiable in severely progressive cases.

Although radioactive iodine was used in the treatment of thyrotoxicosis as early as 1941, the first detailed reports concerning it did not appear until 5 years later. Its use has been limited chiefly to selected cases, most of them of either toxic diffuse goiter (Graves' disease) or recurrent postoperative thyrotoxicosis. Few patients with toxic nodular goiter appear to have been treated. Its effective use is limited at present to a relatively few clinics.

Internal irradiation by the gamma rays results in a gradual reduction of the activity of the toxic thyroid, although this may be preceded by a temporary exacerbation of the disease. Remission may be complete in from 1 week to 6 months, or longer. The incidence of satisfactory end results appears to be somewhere between 70 and 80 per cent, but it should be remembered that most of the reported series have consisted of selected cases. Myxedema with fibrosis of the thyroid may occur, and the ocular complications are occasionally aggravated. Late carcinogenic effect on the thyroid and damage to the urinary tract during excretion are possible dangers which cannot at present be evaluated.

The basic principles of preoperative care of patients with hyperthyroidism are the same, regardless of the type of the disease. The patient should be placed on a program which will tend to (1) bring the basal metabolic rate to normal, (2) improve the general nutrition as demonstrated by a gain in weight and an improvement in the general physical condition, (3) lead to a stabilization of the pulse rate, and (4) finally, but not the least important, restore the patient's confidence in ultimate recovery.

In the severely toxic patient propylthiouracil is administered in amounts varying from 150 to 300 mgm per day, until the metabolic rate begins to approach normal. Ten days to 2 weeks before operation is planned, treatment with iodine is begun in the form of potassium iodide (10 drops of saturated solution, three times a day).

Thiamine hydrochloride, in amounts of 50 to 200 mgm daily, is given in addition to riboflavin, 450 mgm, and nicotinamide, 750 mgm, daily. The

authors also found it useful to give additional vitamin B in the form of a potent yeast concentrate of 3,000 to 5,000 calories a day. The important thing is that the patient eat an amount sufficient to meet energy requirements and have left a modicum for restoration of the depleted body tissues. The criteria of achievement of this objective are a gain in body weight in the absence of edema, and an improvement in general muscular tone.

Even though the pulse rate may remain above normal, a diurnal uniformity of rate is desirable and should be regarded as one of the major objectives of the preoperative preparation. It is facilitated by mild sedation during the preoperative period and by optimal hospital environment.

The staff must be thoroughly conscious of the psychogenic factors that played a part in the initiation or extension of the disease, and of the fears that beset these patients.

In patients who were severely toxic when first seen, and in those who are still easily frightened, the authors employ the method of "stealing the thyroid." On the morning of operation the house officer who has most actively participated in the care of the patient administers thiopental sodium (pentothal sodium) intravenously. The patient, thinking that only another test is being made, goes to sleep unaware that within a few moments the operation will proceed.

Inhalation anesthesia is then administered. The specific anesthetic employed is less important than the prevention of anoxia. Some anesthetic agents, such as cyclopropane, may affect cardiac activity, others, such as ether or ethylene, may affect the liver, but these risks may be accepted as long as anoxia is avoided. Under conditions of anoxia, cardiac integrity may suffer, liver injury may become further accentuated, and a pre existing renal injury may become worse.

Every possible care must be exercised not to injure the recurrent laryngeal nerves. No thyroid resection should be attempted without prior identification of parathyroid tissue. These glands vary in number and in position even in normal persons. Their location may be further distorted by enlargement of the thyroid.

The thyroid isthmus should be divided and the trachea exposed. Sparing the isthmus and pyramidal lobe results in a higher incidence of persistence of hyperthyroidism. A radical resection of both lobes of the thyroid should be accomplished in every instance if a high incidence of permanent cures is to be expected. It is far better to remove too much than too little, for the hypothyroid state which may follow a very radical thyroidectomy is far better and more easy of control than is persistent hyperthyroidism.

The gland should be adequately exposed, if necessary, by division of the prethyroid muscles. Mass ligation of the superior poles is undesirable. It leaves thyroid tissue in amounts that cannot always

INTERNATIONAL ABSTRACTS OF SURGERY

be assessed, and it results in injury to the superior laryngeal nerve, thus predisposing to excessive mucous secretion in the trachea.

Crisis is the most dreaded of the postoperative sequelae. It is now so infrequent that younger surgeons rarely see this complication and may therefore underestimate its importance. Perfect anesthesia reduces the risk of a severe reaction. The intravenous use of dextrose during and after operation assists in reducing its incidence and severity.

When crisis occurs, therapy should be begun at once. The blood volume must be maintained, dextrose and iodine given intravenously, and attention directed to any specific electrolyte imbalance. Large amounts of sodium salts should not be administered if the imbalance is one chiefly associated with potassium disturbance, and neither should be administered without careful study of all components of the vitamin B complex should be given, parenterally, when necessary. Propylthiouracil may also be of assistance.

Acute traumatic parathyroid insufficiency, while rarely fatal, may be an important cause of postoperative morbidity. In many cases the insufficiency is self-limited, and spontaneous readjustment may occur up to 6 months after injury.

The authors report on 655 thyrotoxic patients operated on in the 10 year period prior to June, 1947.

The mean age of the entire group was 40.6 years. Of the total number of patients, 145 (22.2%) were males and 510 (77.8%) were females. Four hundred and fifty-two (69%) of the patients had diffuse toxic goiter and 203 (31%) had toxic nodular goiter, there were 82 patients (12.5%) with serious heart disease, 24 patients had true diabetes mellitus, and 6 had active pulmonary tuberculosis. The average period of preoperative iodine administration while in the hospital was 12.3 days. Many had received iodine for a variable period prior to admission. The mean period of days of thiouracil therapy was 37.2 days, of aminothiazole, 17.5 days and of propylthiouracil, 67.8 days.

The patients with diffuse toxic goiter showed a mean basal metabolic rate of 42 per cent, and those with toxic nodular goiter, of plus 58 per cent. The overall mortality rate was 0.9 per cent.

There were 3 instances of true crisis (0.46%). No patient died in crisis subsequent to the use of iodine plus thiouracil or propylthiouracil in the preoperative period. Twenty-three patients (3.5%) had postoperative impairment of the motion of one vocal cord. Of these 23 patients, 20 recovered completely. Two patients showed evidence of hypoparathyroidism.

The average basal metabolic rate for the entire group at the last follow-up visit was plus 3.7 per cent. Fifteen patients (2.3%) had recurrent thyrotoxicosis.

Amyloid Tumors of the Larynx, Trachea, or Bronchi. A Report of 15 Cases. DAVID B. STARK and GORDON B. NEW. *Ann Otol Rhinol*, 1949, 58, 117.

The clinical features of 15 cases in which the pathologic diagnosis was amyloid tumor of the larynx, trachea, or bronchi were reviewed by the authors. The pathologic features considered characteristic of the tumors are occurrence of the homogeneous concentric-layered masses, and a characteristic reaction of the amyloid material with one or more of the so-called amyloid stains. No concomitant disease considered of etiologic significance was noted. The presenting signs and symptoms of amyloid tumor are dependent on the size and location of the lesion.

Classification of the tumors into the localized variety and the diffuse infiltrating variety is of significance in determining the type of treatment to be employed and the prognosis after treatment.

The localized tumor was surgically removed, with an excellent functional result. The diffuse lesion involving the subglottic region and the upper part of the trachea was removed with immediate grafting of the resultant denuded area. A permanent tracheostoma was avoided, and the functional results were excellent. The functional results obtained by treatment of the diffuse lesion involving the glottis proper were not so satisfactory. The prognosis as to life was excellent, except in some cases of endobronchial lesions. The disease tended to be self-limiting.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS, CRANIAL NERVES

Percutaneous Cerebral Angiography and Cerebral Abscess H. F. FABRITIUS, A. G. FRØVIG, and K. KRISTIANSEN *Arch Neurol Psychiat*, Chic., 1949, 61 352

This report summarizes the etiology, diagnosis, and treatment of 7 cerebral and 1 cerebellar abscesses observed at the Oslo University Hospital. Three of the abscesses were multiple, 2 were metastatic from the lungs, 3 were of otitic origin, and 2 of otitic origin. The main diagnostic aid was percutaneous cerebral angiography which showed dislocated vessels around an avascular or poorly vascularized area representing the abscess.

The authors' treatment consisted of aspiration of the abscess content, local injection of penicillin in the abscess cavity, and systemic as well as intrathecal administration of penicillin and sulfadiazine. In some cases thorotrast or air was injected into the abscess cavity for better visualization. There were 3 fatalities.

GEORGE PERRET, M.D.

Abscess of Brain Due to Clostridium Perfringens Treated with Penicillin RALPH B. CLOWARD *Arch Neurol Psychiat*, Chic., 1948, 60 504

A case report is given of a patient with a fulminating infection of the brain due to clostridium perfringens, which developed after a depressed fracture of the frontal lobe. The patient was treated with operative drainage and with penicillin which was introduced locally into the area of infection through a permanent catheter. The patient was also given 20,000 units of penicillin intramuscularly every 2 hours. A second operative procedure was necessary to clean out further devitalized brain and accumulations of pus. Further treatment with penicillin followed, the patient receiving a total of 2,385,000 units of penicillin, and 95,000 units of this were injected locally into the abscess cavity. The patient made a satisfactory recovery. The author attributes the recovery to surgical drainage of the abscess coupled with penicillin, and points out the specificity of penicillin in the treatment of infections due to the gas bacillus as reported by previous observers.

HOWARD A. BROWN, M.D.

A Contribution to the Study of Chronic Subdural Hematoma (Contribution à l'étude de l'hématome sous dural chronique) G. R. HOFFMAN *Acta chir belg*, 1948, 47 569

It is pointed out that a chronic subdural hematoma usually occupies a position more or less limited to the convexity of a hemisphere. Exceptionally, it may be found between the two hemispheres, over the contents of the posterior fossa, or in the potential subdural extra-arachnoidal space.

A subdural hematoma in the chronic state characteristically consists of a cyst (with two walls) containing a few clots and a liquid which is the result of a breakdown of the blood. It is only when the hematoma has existed for quite some time that the walls of this cyst have a definite character. The external wall is thin and adheres to the dura mater, it shows a massive infiltration of polymorphonuclear cells as well as extensive fibroplasia. The inner wall is usually thin and delicate, it may be found free, but more often it is adherent to the underlying pia mater. It is made up almost completely of fibroblasts. While it is true that such hematomas may arise from congenital vascular malformations, the commonest cause is certainly that of trauma resulting in rupture of, and bleeding from, the veins passing from cortex to dura mater, or a sinus.

The time from the beginning of bleeding to the diagnosis of the clot may be anywhere from 15 days to several months. The author believes that more commonly chronic subdural hematomas present their signs between the third and sixth week. There are various clinical signs, including headache, mental changes, motor dysfunction, pupillary changes, epileptiform seizures, bradycardia, and nausea. Surgically, the author follows the more common surgical procedure, that is, the washing out of the clot through two burr holes. He feels that this simple trephine operation is preferable to the placement of a flap.

JOHN MARTIN, M.D.

Multiple Brain Tumors (Multiple Gehirntumoren) HERBERT KRAUS *Wien med Wschr*, 1949, 99 174

The author states that the occurrence of multiple primary brain tumors is not a rarity and he quotes Bier, of Jena, who stated that 3 to 3.4 per cent of all primary brain tumors are of this type. Six cases are reported in detail, to illustrate the various types of tumors and some of the difficulties encountered.

The first case was one of bilateral acoustic neuroma which, following ventriculography, was considered to be an inoperable midline tumor at the base of the posterior fossa, because of elevation of the posterior third of the third ventricle, the aqueduct, and the fourth ventricle. The author stresses the difficulty of diagnosing bilateral acoustic neuromas because both internal acoustic meati present a regular, symmetrical enlargement and comparisons show no variation. In addition, large or bilateral acoustic neuromas can show a dorsal displacement suggesting a single midline inoperable lesion.

The second case presented both an acoustic neuroma and an undiagnosed small parasagittal meningioma. This is a relatively common combination.

Another patient had Recklinghausen's disease with an acoustic neuroma which was partially scooped out. At autopsy neuromas were likewise

INTERNATIONAL ABSTRACTS OF SURGERY

found in the intercostal nerves and along the roots of the vertebral canal

The fourth individual was only operated upon at his expressed wish, and bilateral acoustic neuromas were shelled out. At autopsy on the following day several small meningiomas were found over the left cerebral hemisphere and over the right parietal lobe. In addition to the bilateral acoustic neuromas there were similar lesions in the right olfactory bulb, left trochlear nerve, oculomotor, glossopharyngeal, and vagus nerves, bilaterally, also in numerous intercostal nerves, the brachial plexus, and the right radial and femoral nerves bilaterally. The condition was diagnosed as Recklinghausen's disease with multiple meningiomas. It is believed that a biopsy should be made in every case to substantiate the diagnosis of Recklinghausen's disease. The prognosis is poor, and usually operation should not be attempted.

In the fifth case, 12 meningiomas, totaling 200 gm., were removed from the brain along with simultaneous excision of one meningioma from the spinal cord. In spite of the necessary radical surgery the patient survived and was in fair general condition. The final case reported was one in which a spongioblastoma was found to be present in the left and right thalamus, with another glioma at the seventh thoracic vertebra. It is very unusual to find multiple glomatous tumors in both the brain and spinal canal.

RICHARD C. SCHNEIDER, M.D.

Analysis of Electroencephalographic Findings in 40 Cases of Varied Brain Tumor. Electroencephalographic Findings in Meningiomas. HENRY M. CUNEO, CARL W. RAND, and H. SJAARDEMA. *Bull. Los Angeles Neur. Soc.*, 1949, 14, 1

In this first of a series of articles an analysis is made of electroencephalographic studies of 10 meningiomas which were exactly localized either by surgery or autopsy.

It was found that electroencephalographic tracings localized the tumor correctly in 3 instances—in the left frontal, the right frontal, and the right occipital regions. Localization was mistaken in 1 case in which a right midfrontal tumor weighing 117 gm. was localized in the right temporal region. In the 4 other instances the tracings were not localizing, in these cases the tumors were located in the left sphenoidal ridge, the right parasellar region, the left parasagittal region, and in the subtentorial midline. The electroencephalographic tracings showed slow waves, phase reversals over the seat of the lesions, or both.

Clinically accurate localization was made in 6 cases. The tumor could not be localized in 2 cases and was wrongly localized in the 2 other cases in which the electroencephalograms had also failed. Ventriculographic studies were made in 6 cases, including the 4 in which correct clinical localization was impossible, and permitted accurate diagnosis. In this study the electroencephalographic tracings failed to provide any diagnostic advantages, they

confirmed a correct clinical diagnosis but did help in 1 case which could not be clinically localized. GEORGE F. PERRET, M.D.

Operative Restoration Following Facial Paralysis (Die operative Wiederherstellung der Facialis-mungen). OTTO LORENZ. *Z. f. Forsch.*, 1949, 107

The author has briefly reviewed the causes of facial paralysis and listed them in the following groupings: (1) mechanical (traumatic and postoperative), (2) inflammatory, (3) bacterial or toxic, and (4) rheumatic (70 per cent of total). Consideration is given to the most opportune time for restorative surgery following facial paralysis. Too early operation is not deemed advisable, and the author suggests that the appearance of reaction of muscle degeneration should probably be the criterion for the timing of the procedure. In addition, the neurologist and the otologist should be consulted for their opinions.

There are four fundamental methods of operative reconstruction, and the advantages and disadvantages are discussed very completely. They are:

1. The removal of local scarring of the nerve in the petrous bone, with the bridging of the gap by means of a free nerve transplant or, in rare cases, by primary nerve suture.
2. Anastomoses of the facial nerve with the spinal accessory, glossopharyngeal, trigeminal, or, preferably, the hypoglossal nerve. Under this heading the direct neurotization of the paralyzed facial muscles by the hypoglossal nerve was considered and discarded.
3. The removal of antagonistic nerve supply by cervical sympathectomy, and mechanical supply by suspension with wires, fascers, various plastic substances, and myoplastic procedures.
4. Muscular neurotization, which method is elected as the treatment of choice.

In muscular neurotization, described and used by Lexer and Rosenthal, the paralyzed muscle is neurotized by the implantation of a well innervated muscle bundle. Usually two bundles are dissected free from the temporal muscle and implanted in the musculature of the upper and lower eyelids. Three more flaps are cut from the masseter muscle and curved upward to the alar nasae and to the orbicularis oris at the upper and lower lip. The first movements are noted in from 4 to 6 weeks after operation. Good results may be expected if the operation is carried out within 2 years after the development of paralysis.

In the West German Oral Surgery Clinic, this procedure has been used with much success. The method is regarded as one of the great advances in restoration of function in facial paralysis, for it does away with unsightly associated movements.

Although the latest reference cited in the bibliography is 1940, this article offers an orderly and comprehensive review of the topic.

KENNETH C.

SURGERY OF THE NERVOUS SYSTEM

SPINAL CORD AND ITS COVERINGS

Intervertebral Disc Hernias of the Cervical Region
(Les hernies discales de la région cervicale) J-A
LIEVRE *Presse méd*, 1949, 57 303

The author has reviewed the previously reported history and clinical studies relating to the cervical disc and has appended rather a complete biography to his article.

He points out that the most frequent locations for such herniations are at the fifth and sixth interspaces, but that they may also occur in the third, fourth, and seventh interspaces. Even double herniations may occur. Such herniations occur most commonly in middle age, oftener in men than in women, frequently follow injuries of one sort or another, and may be accompanied by a secondary arthritis, per se, malalignment of the vertebrae. He points out also, in that connection, that cervical arthritis, per se, may simulate the syndrome of herniated cervical disc. While it is true that the "typical" herniated disc produces a single root syndrome of pain, numbness, and selective dermatome and myotome defect because of the fact that the cervical roots leave the cord at a right angle and pass directly out between the corresponding vertebrae, nevertheless a disc large enough and centrally enough placed will give definite cord signs, and such a lesion must be thought of in the differential diagnosis of lesions of the cervical cord. Mild increase in the total protein may be present in either type of cervical disc.

The author does not feel that medical treatment such as rest, physical therapy, local anesthesia, antihistamine injections, or collars give the patient much hope of relief, and probably none of cure. He believes that the proper treatment in most cases is cervical hemilaminectomy and removal of the disc.

JOHN MARTIN, M D

PERIPHERAL NERVES

Late Paralysis of the Ulnar Nerve and Occupational Accident (Paralysie tardive du nerf cubital et accident du travail) ALBERT MOUCHET and GUY SEILLÉ *Presse méd*, 1949, 57 197

A carpenter, 63 years old, experienced isolated paralysis of the right ulnar nerve with complete degeneration after a heavy piece of iron fell on his hand. The history revealed that at the age of 4 years he had suffered a fracture of the external condyle of the humerus with subsequent deformation of the joint and progressive cubitus valgus. However, until the recent accident, the patient was able to use his right hand fully in his heavy work and did not experience any particular weakness.

The nerve was disengaged from adhesions and transposed anteriorly of the epitrochlear muscles. The paralysis gradually decreased after the operation.

The long interval of 50 years between the fracture and the onset of the paralysis is remarkable. The author discusses the role of the recent occupational

accident in the development of the paralysis. He believes that degeneration of the ulnar nerve, caused by pressure of the displaced condyle, had begun long before the new accident without causing subjective symptoms. The new traumatism acted as a kind of trigger mechanism and aggravated the condition so that the paralysis became manifest.

WERNER M. SOLMITZ, M D

Traumatic Lesions of the Sciatic Nerve and Its Branches. An Anatomicoclinical Study of the Therapeutic Results in 53 Cases (Lésions traumatiques du nerf sciatique et de ses branches. Étude anatomoclinique et résultats thérapeutiques d'après 53 cas) R. FONTAINE, A. DAVY, and PH. SCHUMACHER *Lyon chir*, 1949, 44 185

This report concerns 31 patients with traumatic lesions of the sciatic trunk, 13 with lesions of the peroneal, and 9 with lesions of the tibial nerve.

The authors have categorized the results of their clinical studies rather differently from the manner in which these lesions are studied in America. They lay particular stress on the trophic changes which occur with such lesions, both in the skin of the foot and in the bones of the toes. They have found that surgical suture rarely gives 100 per cent functional results and that one must wait 2 or 3 years, at least, before the final end point is reached after such surgery. They believe that fresh heterografts are more effective than a preserved heterograft, but that autografts are by all odds more effective when grafting is necessary. Nevertheless, they feel that suture by graft or end-to-end proximation (the latter always being ideal if possible) is the beginning point in the rehabilitation of a patient with such a lesion. They stress a long follow up on patients with sciatic nerve lesions for a true evaluation of spontaneous or post-surgical recovery.

JOHN MARTIN, M D

MISCELLANEOUS

Causalgic Syndromes W V MACFARLANE *Austral N Zealand J Surg*, 1949, 18 191

Causalgia in general is discussed by the author and the theoretical considerations advanced to explain this phenomenon are further listed. A summary of previous reports and work in regard to causalgia is included, and a classification of the syndromes included under this category is given.

The author's method of attack included attention directed toward ascertaining the level in the pain conduction pathways, at which section would lead to relief of pain. They have used local anesthetic infiltration into painful scars and tender subcutaneous areas, and injections of the sympathetic chain, as well as of nerve trunks and roots proximal to the site of the injury. Sympathectomy was undertaken if local blocks appeared successful. Posterior rhizotomies were also used in some cases. Chordotomy has also been used.

The author believes that the absence of burning pain does not exclude the diagnosis of causalgia.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Testosterone Propionate in the Treatment of Breast Cancer SIGVARD KAAE *Acta radiol*, Stockh, 1949, 31 97

This is a report of the use of testosterone propionate in 15 cases of breast cancer observed over a period of 10 months or longer. All the patients had osseous metastases and all were women in whom the menopause had begun. It is concluded that, without doubt, in many cases of breast cancer with metastases to bones there is a temporary, but marked, relief from pain, associated with considerable improvement of the patient's general condition following treatment with testosterone propionate.

Sometimes, and especially in cases in which there is initial hypercalcemia, the therapy may give rise to toxic manifestations. Therefore, the patient should be observed carefully, particularly after the first injections, and the serum calcium controlled. However, if it rises to high values the treatment will have to be discontinued. In women in whom menopause has been present before the institution of the therapy, just as good effects can undoubtedly be obtained, and more readily, by roentgen irradiation of the ovaries, and the testosterone can be reserved for a later time.

STEPHEN A. ZIEMAN, M.D.

TRACHEA, LUNGS, AND PLEURA

Surgical Extrapleural Pneumothorax in the Treatment of Large Tuberculous Cavities at the Upper Lobe of the Lung G. L. RONZONI *J internat chir thor*, 1949, 1 75

In this first experimental series of cases the problem of an expedient indication for extrapleural pneumothorax is studied with regard to the treatment of large tuberculous cavities in the upper lobe of the lung. By expedient indication the authors mean an indication to be substituted for the more theoretical, but correct one either because of the evolution of the disease, or because of the condition of the patient.

A technique of extrapleural stripping is described. It permits the performance of a pneumothorax with particular features which allow either a hypotensive or hypertensive method of maintenance and a progressive graduation of the pulmonary collapse. It is being proposed to call this special type of intervention a "subtotal lateral mediastinic extrapleural pneumothorax," adding "hypotensive" or "hypertensive" as the need may be.

JOHN J. MALONEY, M.D.

Experimental and Clinical Study of Collapse Therapy with Fiberglass Wool and Fabric THOMAS J. O'NEILL, HECTOR P. REDONDO RAMIREZ, and ROBERT G. TROUT *J Thorac Surg*, 1949, 18 181

Experimental studies were undertaken with a combined series of 20 dogs. Two procedures were

used. In one series, extrapleural packing of fiberglass raw wool was used. This resulted in tissue reaction which was regarded as unsatisfactory. In the second series, fiberglass fabric was used intrapleurally, to invest a selected lobe. This proved satisfactory as an excellent selective atelectasis was accomplished and the implantation of the material occasioned only a minimal tissue reaction.

Ten case histories are reported. In 3 cases, the upper lobes were wrapped in fiberglass fabric to accomplish selective collapse and in 7, extrapleural pneumonolysis was done, and the created space was filled with fiberglass wool. In 1 case the raw wool alone was placed in the space. This resulted in the same kind of tissue reaction as seen in the experimental animals, in which there was considerable foreign body response, this foreign mass became infected and had to be removed. In the remaining 6 cases the space was first lined with fiberglass fabric (which in the dogs was shown to be practically non-reactive) and then the lined space was filled with raw fiberglass wool. No infections resulted in these cases and the collapse was regarded as satisfactory.

SAMUEL KAHN, M.D.

An Evaluation of Extrapleural Pneumonolysis with Lucite Plombage JOSIAH C. TRENT, JAMES D. MOODY, and JOSEPH S. HIATT, JR. *J Thorac Surg*, 1949, 18 173

Extrapleural pneumonolysis with plombage is a desirable operation because (1) it can be done in one stage, (2) it is technically easy, (3) it is well tolerated, (4) there is no deformity of the chest, (5) the function of good lung tissue is maintained, and (6) the hospital stay is short.

The ideal material for insertion in the extrapleural space, to maintain pulmonary collapse, has not yet been found because of the susceptibility of the extrapleural space to infection. Air, oil, and paraffin have been the most successful, however, their use is limited to highly selected cases in which thoracoplasty is not indicated. Experimental studies seemed to indicate that lucite spheres approached the ideal plombage substance, but clinical trial has failed to substantiate the early promise of the operation.

Dense hyaline tissue was found to form around the spheres in the experiments, as well as in 3 clinical cases in which no infection occurred. Since lucite is an inert material in the body, the probable explanation for this tissue formation lies in the spherical shape of the plastic material, which allows sufficient space between the spheres for serum to accumulate, clot, and organize. When this dense hyaline mass forms, it is very difficult to remove the spheres, unless infection and liquefaction of the surrounding tissue occur. Lucite plombage must, therefore, be a definitive procedure since, if it is not successful, no other operative procedure is feasible as the success

of the latter is dependent upon the removal of the spheres

Of 51 patients on whom extrapleural pneumolysis with lucite plombage was carried out, 10 were benefited, 3 received no benefit, 20 were adversely affected, and 18 died. The late results of the operation do not justify continuation of the procedure

SAMUEL KAHN, M D

The Malignant Nature of Bronchial Adenoma

ALFRED GOLDMAN *J Thorac Surg*, 1949, 18 137

Five cases of bronchial adenoma which showed malignant qualities are reported. The most malignant changes to occur were found in the mixed tumor type of bronchial adenoma. The complete transformation to a clinical and histological picture of bronchiogenic carcinoma has been observed. Carcinoma of bronchiogenic origin may, at times, arise in a mixed tumor type of bronchial adenoma. Carcinoid types of bronchial adenoma not infrequently show metastatic involvement of the mediastinal lymph nodes. This may occur when the tumor has been present for as long as 30 years, or when the duration of symptoms has been only a few months.

The finding of bronchial adenoma in conjunction with multiple tumors of low grade malignancy in other organs suggests that the stimulus for the production of bronchial adenoma is the same as that capable of producing neoplasms in other organs than the lung. The failure of bronchial adenoma to produce vascular seedings, even though the tumor cells were demonstrated floating in the lumen of a large pulmonary vein, suggests that the only favorable soil for bronchial adenoma is in the bronchi and lungs.

The treatment of bronchial adenoma by lobectomy and pneumonectomy has given approximately 100 per cent 5 year cures, when this period of time has elapsed since operation. SAMUEL KAHN, M D

Pneumonectomy in a Case of Besnier Boeck's Sarcoidosis

C L PETERSON *Arch chir Neerl*, 1949, 1 64.

A careful search of the literature has revealed no mention of surgery performed for irreversible pulmonary changes in Boeck's sarcoidosis.

Ordinarily, surgery in this disease may be considered as contraindicated or unnecessary, because of the universal distribution of the sarcoidosis throughout the body and the usual bilateral reversible pulmonary manifestations. However, there is one development of the pathology which may demand such an intervention.

In the latter stages of the pulmonary involvement a tendency toward fibrosis and healing may occur. This fibrosis in rare instances may take a pernicious course with gradual interference in the normal pulmonary physiology. Involvement of the bronchi and bronchioles may produce severe stenosis with interference in the air passage resulting in atelectasis. Involvement of the pulmonary arterioles and capillary bed by the fibrosis may consecutively cause

narrowing of the vessels, mechanical obstruction of the blood flow, pulmonary hypertension, cor pulmonale, congestive heart failure, and, ultimately, death. Distortion and stenosis of the bronchi, further, may predispose to pulmonary infection of either an acute or chronic nature with a fatal termination.

Surgery may be precluded by the presence of bilateral involvement by the progressive disease process or by the localization of the lesions in other organs. These intrapulmonary and extrapulmonary deposits may be so extensive and may have so debilitated the patient that interference may be unwise. However, a patient with an irreversible lesion, unilaterally placed, with minor or no involvement elsewhere, and presenting sufficient symptomatology to justify surgical intervention, prior to the cardiac sequelae, should be considered as a possible candidate for lobectomy or pneumonectomy.

One such patient who presented these conditions was treated at this clinic and the author considers that the case may be of interest in view of its rarity and because of the gratifying results obtained.

The patient's marked general improvement after operation was dramatic. One year after the pneumonectomy the disease continues to remain in a quiescent state with no evidence of pulmonary recurrence.

The pulmonary form of Besnier Boeck's sarcoidosis is briefly discussed.

A rare case with subsequent resolution of the lesions throughout, except in a localized area involving the left upper lobe, is presented.

JOHN E. KIRKPATRICK, M D

The Clinical Use of a Prosthesis to Prevent Overdistention of the Remaining Lung Following Pneumonectomy

JULIAN JOHNSON, CHARLES K. KIRBY, C S LAZARIN, and J A COCKE *J Thorac Surg*, 1949, 18 164

Lucite balls placed in the pleural cavity of dogs following pneumonectomy prevented mediastinal shift, and were well tolerated, as evidenced by autopsy studies 1 year after the operation.

In 8 patients in whom lucite balls were placed in the pleural cavity after pneumonectomy, the mediastinum has remained in the midline, and there have been no apparent complications resulting from the presence of the balls.

The use of a lucite ball prosthesis may be a simple and effective method for preventing overdistention of the remaining lung following pneumonectomy.

SAMUEL KAHN, M D

Pyogenic Empyema with Extension Below the Diaphragm

WILLIAM LEHMAN GUYTON and HOWARD W JONES, JR *South M J*, 1949, 42 359

The authors add 3 new cases of pyogenic empyema to the 12 already described in the literature. The anatomic pathways by which the infection spreads through the diaphragm are discussed. In the first 2 cases the drainage tract extended along the course of

SURGERY OF THE THORAX

the medial and lateral arcuate ligaments. In the third case, erosion of the diaphragm occurred without following the anatomical spaces. This patient survived the operation and was treated with antibiotics which perhaps offer a more hopeful prognosis inasmuch as the mortality rate to date, in the reported cases, is 50 per cent.

STEPHEN A. ZIEMAN, M.D.

HEART AND PERICARDIUM

The Surgical Treatment of the Patent Ductus Arteriosus P. DECKER, *J. internal chir. thor.*, 1949, 1, 63

The three different methods of surgical treatment of the patent ductus arteriosus are described.

1. Ligation of the ductus by two strong, braided silk ligatures, one placed near the aorta and the other near the pulmonary artery. Such a technique, as the simple ligature, has resulted in a relapse of the ductus. That is why the injection of a hypertonic glucose solution into that part of the ductus between the two ligatures has been associated with the double ligature. Also, after placing the two ligatures the occlusion was reinforced by tying over them a small knot similar to that used to ligate the umbilicus, or by wrapping them in cellophane.

2. When the ductus is long enough it is dissected as widely as possible, and then its two ends are ligated with two strong, braided silk ligatures. Two or more transfixed ligatures are placed on the portion of the ductus between the two main ligatures.

3. Resection of the ductus (Gross' technique). The ductus is approached by the anterior route. At first it is dissected along its externoanterior surface, then it is grasped with a blunt clamp. Two unfastened silk knots are placed around it. By pulling first one knot and then the other the ductus can be stretched during dissection. The anterior surface is stripped of its pericardium fold. The ductus is thus afforded an amazing length partly resulting from the fact that by the alternate traction there has been some trespassing upon its aortic and pulmonary artery junctions. The most difficult stage is that of the dissection of the posterior surface. Even when performed by a skilful and experienced surgeon such as Gross the dissection of the posterior wall is long and difficult.

When the ductus has reached a sufficient length, 4 small Crile clamps are placed on it side by side (actually they are special, narrow, blunt clamps). The ductus is then resected between the two clamps in the middle. The middle clamp on the pulmonary stump is removed, and a narrow collar of the ductus wall is exposed. This collar is sutured forward and backward with a thin silk thread and in a traumatic needle. The same procedure is carried out with the aortic end of the ductus, and then the two remaining clamps are removed. After making sure of the stanching of the sutures, Gross places a muscle flap from the thoracic wall between the two lines of obliteration.

Which of these three techniques is the best one? It is difficult to answer this question by a single word. Gross's operation is a magnificent surgical achievement affording security against relapse. But even when it is performed by its creator one cannot help realizing its magnitude. In older subjects with stiffer tissues and more sclerosed vascular walls it is, according to Gross, a dangerous operation. The same can be said when it is used in cases of viridans streptococcus arteritis in which the vascular walls may be extremely brittle. It seems to the author that the real difficulty of Gross's operation lies not in the suture of the vascular stumps, but rather in the dissection of the ductus over a sufficient length to enable the placing of the four clamps.

The author is convinced that for a beginner in this type of surgery, resection of a patent ductus arteriosus according to Gross' technique should be restricted to very "good risk" patients, i.e., patients having a somewhat long fistula.

The surgeon performing his first operation for patent ductus arteriosus should, in the opinion of the author, prefer the multiple ligature, at least in the case of short ductus, and resort to resection only when he has acquired a wide experience in this field.

JOHN J. MALONEY, M.D.

Surgical Treatment of Persistent Ductus Arteriosus (Traitement chirurgical de la persistance du canal artériel) DE VERNEJOUL AND H. MÉTROS, *J. chir.*, Par., 1948, 64, 497.

The authors present a brief review of the history of the surgical treatment of persistent ductus arteriosus from the time of its suggestion by Monroe, in 1907, its first clinical application by Graviel, Strieder, and Boyer, in 1937, the first successful operation by Gross, in 1938, and the first successful operation in a case complicated by endocarditis, by Tourouff and Tuchmann, in 1940. In the past 8 years we have seen chiefly modifications of the technique, with preference for section of the duct, since ligation was followed frequently by recanalization. The chief elements of diagnosis of the technique, emphasis on the fact that the continuous murmur can be considered as a conclusive sign of patent duct, only if phonocardiographically demonstrated. It is stressed that the incidence of this anomaly is greater than has been suspected. Most of the patients with this anomaly, if not operated upon, die early or succumb later to endocarditis, the average age at death being 24 years. Prognosis is especially poor in the presence of signs of decompensation.

The elective age for operation is 3 years. The operative mortality is 5 to 10 per cent in noninfected cases, and 50 per cent in infected cases. The details of technique as practiced by leading English, American, and Swedish surgeons are discussed, and the criteria for the selection of ligature or section are indicated.

Ligature may be followed by recanalization, and may lead to sclerosis involving the recurrent nerve and thus cause lasting dysphonia. The wall of the

canal may be fractured and lead to arterial thrombosis by fracture of the intima, or to aneurysm desiccans by fracture of the media. The type of the canal is also a factor in determining the type of treatment. In the case of a large arteriovenous fistula, section and suture are obligatory.

The results of ligature and resection in noninfected and in infected cases reported by various authors, are summarized. Among 734 patients without infection there were 37 deaths, and among 141 patients with infection there were 17 deaths. Gross considers section of the duct as the only certain method of preventing recanalization. In adults from 18 to 20 years of age, section followed by suture is recommended, whereas in young children, ligature may suffice. Postoperative care and the incidence of complications during and after operation are discussed on the basis of reported cases.

EDITH SCHANCHE MOORE

The Operative Management of Aortic Coarctation
(Die operative Behandlung der Isthmusstenose der Aorta) FR BERNEARD *Chirurg*, 1949, 4 145

This article is mostly concerned with the case history of a 15 year old male with coarctation of the aorta who was successfully operated upon by the author. In connection with the case, the author presents a discussion of the electrocardiographic findings (extrasystoles, lowered ST segments, and myocardial damage), the clinical picture (a blood pressure of 220/230 Hg of mercurv), the roentgenographic picture (notching of the ribs where the collateral circulation develops), photographs of the surgically removed coarctation segment, and a well integrated review of the literature on the subject of coarctation.

In presenting the technique, the author includes a rather clever, side-to-side anastomosis technique which might be used in cases in which the aorta is more or less angulated at the point of constriction.

JANE C. MACMILLAN M.D.

berard) Sketch of side-to-side anastomosis proximal and distal to the coarctation

A Case of Aneurysm of the Aorta after Resection for Coarctation Cured by Excision J R. BLICKMAN
Arch. chir. Neerl, 1949, 1 50

The surgical interest in the subject of coarctation of the aorta has developed after Crafoord and Nylin and Gross published their cases in 1945. Prior to that time the interest was mainly from a casuistic point of view.

It appears that rupture of the aortic wall is the most frequent cause of death (Abbott), and it seems a well established fact that the aortic wall shows changes, especially near the site of constriction. Although most aneurysms have been described proximal to the coarctation, the severest changes of the aortic wall have been found distally. Recently the circumscribed lesion in the aortic wall distal to the constriction has been named by Edwards and his coworkers at the Mayo Clinic as the "jet lesion." On examination of the aortic wall in cases of coarctation they found a well defined lesion of the intima and media. This they considered to be the result of a constant "jet" of blood being squirted through the narrow opening in the constriction, which hit the wall and caused a traumatic lesion.

Several of the aneurysms showed a penetrating tendency toward the surrounding tissues. In 5 older cases cited by Abbott the aneurysm perforated into the pleura, mediastinum, and lung. One of these terminated in a fatal pulmonary hemorrhage.

Leudet, Reifstein *et al* compiled 5 cases of infiltrating aneurysms with open connection with the bronchus. In these cases the aneurysm was always found distal to the constriction.

The first case of a primary aneurysm at the site of the coarctation which was treated by resection was reported in 1948 by Schumacher. Crafoord *et al* reported 1 case with death after resection caused by a false aneurysm, in their opinion death resulted from insufficiency of the aortic suture line.

The author reported this case as an example of the complications which may be expected more frequently as more of this surgery is performed.

A 20 year old girl was, until 1946, free from complaints, even in wartime during which she was in a Japanese concentration camp. On examination blood pressure of 210/110 in the arms and 150/130 in the legs was found. She complained of persistent headache and dizziness.

In May, 1947 an operation was performed by Crafoord in Stockholm. Resection of approximately 1.5 cm of the aorta with end-to-end suture was performed. It was not possible to resect the entire constricted area, as the aorta was narrowed over a distance between 4 and 5 cm.

Approximately 12 hours after operation a very severe hemorrhage occurred in the mediastinum and pleura, which was controlled by blood transfusions.

The diagnosis of aneurysm was made during convalescence. Further steps were not undertaken as no progression of the size of the aneurysm was found and little or no pulsation was observed. After the patient was discharged the general condition was not

SURGERY OF THE THORAX

improved. There was no improvement in the headaches and dizziness. She was practically bedridden and only able to move about at home. The blood pressure at that time had improved (160/90 in the arms, 185/140 in the legs).

In March, 1948 the patient suffered a severe pulmonary hemorrhage and the diagnosis of aneurysm was confirmed. On bronchographic examination it appeared that the lung was involved in the process.

On admission to the surgical department of the University Hospital at Amsterdam the well nourished girl in no acute distress was found to have a blood pressure of 190/95 in the arms and 180/130 in the legs. On inspection she showed the scar of the previous operation on the left side of the thorax. A systolic murmur was heard over the heart and posteriorly to the left of the spinal column. The laboratory findings revealed the hemoglobin to be 70 per cent, and the erythrocytes to number 3,790,000.

On June 18, 1948 an operation was performed by Boerema with the assistance of Vermeulen-Cranch, anesthesiologist. The patient was placed in the right lateral position and the thoracotomy wound was reopened. There was scarcely any hemorrhage. The upper lobe was free. A tumor, the size of an orange, was found in the hilar region and was situated behind the lung in the hilar region and was situated on the descending aorta distal to the left subclavian artery. Commencing laterally, the aorta with its surrounding scar tissue was mobilized. This was especially difficult posterior to the aorta where adhesions with the vertebral column were very dense. It was not possible to free the aorta from the surrounding scar tissue. Two aortic clamps were placed above and below the aneurysm in such a way as to include the surrounding scar tissue. As the tumor was freed from the lung, rupture occurred. The clamps were tightened and bleeding was controlled. The aneurysm was opened and found to be filled with an old organized and fresh thrombotic mass. There was an open communication with the aortic lumen by way of a longitudinal slit, about 2 cm in length. This slit was closed by means of a continuous silk suture. Two flaps from the wall of the aneurysm were used to cover the suture over a piece of gelatin foam. The clamps were removed. Careful closure of the pulmonary lobe defect was done. A wide open bronchus, about 4 mm in diameter, was found. This was the perforation of the aneurysm in the bronchus and therefore the cause of the pulmonary hemorrhages. The opening was sutured. The thorax was closed. The postoperative course was uneventful. A slight hoarseness in speaking was caused by a paralysis of the left vocal cord. It is obvious that the recurrent nerve must have been caught in the clamp at operation.

The fact that it was not possible for the author to determine exactly the location of the slit makes all considerations about the cause highly theoretical. He feels fairly certain, however, that this longitudinal slit cannot be simply the result of insufficiency of the suture line. Whether the tension on the

aorta was sufficient to damage a degenerated aorta in the wall of the vessel, or whether some mechanical trauma in clamping was the causative factor cannot be shown.

Pathological examination of the aneurysmal wall showed complete aortic wall structure with fresh and organized thrombotic masses. From this the author could conclude that in his case a true aneurysm had formed at or near the site of anastomosis.

The invasive behavior of the aneurysm was not uncommon. The fact, however, that a bronchus was found to be wide open after resection of the infiltrating part of the aneurysm clearly showed that for at least 2 months (date of the first pulmonary hemorrhage) an open communication had existed between the aortic lumen and the bronchial tree.

Recently the patient was re-examined. The general condition had improved considerably. The blood pressure readings were the same as on discharge. Headache, dizziness, and hemorrhages were no longer present.

The article is adequately illustrated.

JOHN E. KIRKPATRICK, M.D.

ESOPHAGUS AND MEDIASTINUM

Surgical Treatment of Megadolichoesophagus, Esophagogastrostomy of Necessity or on Principle (Chirurgie du megadolichoesophage esophagogastronomie de nécessité ou de principe) JEAN PATEL and JEAN PAUL BINET *Presse med*, 1949, No 20 268

The authors attempt to demonstrate whether Heller's cardiomyotomy as a treatment for megadolichoesophagus deserves the high reputation it enjoys in France, or the relative disrepute into which it has fallen in America. Many writers have found the Heller operation satisfactory provided the myotomy is sufficiently extensive. Most of these surgeons, although not seeking a substitute operation, make an accessory unilateral resection on the left side, or a bilateral resection of the splanchnic nerves. This intervention evidently does not give satisfactory results. In America, the two most popular operations for this condition have been esophagocardioplasty with successful results in 93 per cent of cases, and esophagogastrostomy, which was first suggested by Gosset, in 1903. The fact that this operation is more time consuming has little weight under present conditions of surgery. Some writers have stipulated that in decubitus this procedure facilitates a reflux of gastric contents leading eventually to development of peptic ulcer of the esophagus. It would seem, therefore, that further statistics will be needed to demonstrate the superiority of one or the other of these operations.

The question is then approached as to the procedure to be followed in the event that a cardiomyotomy with adequate myotomy and supplementary splanchnicectomy has not yielded the desired result. Is further surgery justifiable? The authors answer the affirmative, but here again arises the question

the upper mediastinum eventually proved fatal. Except for the large recurrent mass which grew into the upper part of the esophagus, compressed the trachea, and involved the right lower cervical and upper mediastinal lymph nodes, no other tumor was found at autopsy. SAMUEL KAHN, M D

Thymectomy in the Treatment of Myasthenia Gravis Report Based on 32 Cases L M EATON, O THERON CLAGETT, C ALLEN, and JOHN R McDONALD *Arch Neur Psychiat, Chic*, 1949, 61: 467

According to the authors, the pathologists have accumulated convincing evidence that there is some relationship between myasthenia gravis and the condition of the thymus gland.

Proper roentgenologic technique reveals evidence of thymic tumor in approximately 15 per cent of patients who have myasthenia gravis. Evidence has been presented to substantiate the claim that this figure closely approximates the true incidence of thymic tumor in this disease.

An analysis of the results obtained in 15 patients who had myasthenia gravis and associated thymic tumor, and in 17 patients without thymic tumor who underwent operation for removal of the thymus gland shows that 60 per cent of patients were improved $4\frac{1}{2}$ years to one-half year after operation. Although these results are encouraging, they must

not be looked on as conclusive evidence that thymectomy is of value in the treatment of myasthenia gravis, since the course of myasthenia gravis cannot be predicted with sufficient certainty to make it possible to say that remission would not have taken place spontaneously in these cases.

At least, in certain cases in which myasthenia gravis is associated with thymic tumor, the tumor is present before the onset of the symptoms of myasthenia gravis.

On the basis of this study it would seem that roentgen-ray irradiation of the thymus gland may be of value in treatment.

At present, no significant correlation can be made between the result obtained and the duration of the disease, the length of preoperative treatment with neostigmine, or the histologic observations made by the authors in a study of the thymic tissue removed.

The problem of determination of whether a thymus gland removed at operation is or is not hyperplastic is not a static one. Such designations must be considered tentative at this time.

A conclusive opinion as to the value of thymectomy in myasthenia gravis awaits the careful study of a larger number of cases over a longer period, and a comparison of the course in this group of patients treated surgically with the course of a control group receiving medical treatment only.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Incidence of Hiatus Hernia and Associated Lesions Diagnosed with Roentgen Ray IRVING B BRICK *Arch Surg*, 1949, 58 419

An evaluation of the frequency of hiatus hernia diagnosed with roentgen rays was undertaken and at the same time the type and frequency of accompanying lesions were determined. Among 3,448 barium studies of the upper gastrointestinal tract there were found 308 hernias of the esophageal hiatus, an incidence of 8.93 per cent. The diagnosis of this lesion was second in frequency to duodenal ulcer and more than twice as frequent as gastric ulcer or gastric carcinoma. In 1 of every 4 cases of hiatus hernia associated gastrointestinal lesions were diagnosed, which could have been responsible for the clinical picture. There were also 5 cases in which an ulcer niche or crater was noted within the herniated portion.

Clinical study would no doubt reveal that the hiatus hernia was a coincidental finding as regards the explanation of symptoms in some of these cases. On the other hand, the hiatus hernia should not be overlooked as a potential source of symptoms because another gastrointestinal lesion is present. Some of the associated lesions, such as duodenal and jejunal diverticula, are usually, but not always, thought of as being asymptomatic. There is no easy method of determining, in the presence of such combinations, which lesion is productive of the patient's symptoms, since either lesion alone may produce them. Observation and careful attention to the clinical course under treatment will usually uncover the answer to this perplexing problem.

JOHN L. LINDQUIST, M.D.

Revascularization Following Experimental Mesenteric Vascular Occlusion RUDOLF J. NOER and JOHN WILLIAM DEER *Arch Surg*, 1949, 58 576

The authors made preparations for injection of the vessels supplying the small intestine in the dog, opossum, and man. The injections were carried out in some instances with liquid latex and in others with India ink. The human specimens were obtained at autopsy, while the animals studied were anesthetized and the injections were carried out during life. Three types of mesenteric vascular interruption were carried out in each species: (1) ligation and division of the intestinal arteries alone to 15 cm loops, (2) ligation and division of the intestinal arteries to 15 cm loops plus the arcuate vessels at the extremities of these loops, and (3) ligation and division as in (2) with the added interruption of all the vasa recta to the segment. Injections were made at pressures between 100 and 150 mm, to approximate the normal arterial pressures. In each type of vascular interruption it was found that the injection produced

vascular filling in loops about 15 cm long. In the third type of vascular interruption the dog was the only animal in which some specimens failed to fill completely at the central portion of the deprived loops.

The intramural circulation contains communications of three general types: (1) direct cross communication between the mural trunks, (2) "plexiform" anastomoses in which the adjacent vessels break up into fine radicles and then anastomose with each other, and (3) arcuate communicating vessels which run parallel to the long axis of the intestine to connect the adjacent mural vessels along the side of the intestine, usually near the antemesenteric border. The first type is best seen in the human intestine and also in that of the opossum. The dog shows chiefly the plexiform type and has direct anastomoses between the mural vessels. It is the authors' impression that this situation best explains the poorer filling seen in the dog loops injected after mesenteric vascular deprivation.

The authors are convinced that the injection method is a convenient one for studying routes available for revascularization, since there is sufficient correlation between survival in animals and the ability to inject such loops to justify inferences based on the results of injection studies. Since the intramural circulation appears to be such an important factor in revascularization, the authors suggest that distention is an obvious hazard to revascularization.

HAROLD LAUFMAN, M.D.

GASTROINTESTINAL TRACT

A New Operation for Gastropotosis ANTON RAABE *Acta chir scand*, 1949, 98 40

The author protests the disregard paid in the recent surgical literature to gastropotosis. The symptoms which the author considers as indications to surgery are: (1) an x-ray view showing a ptosis with the lesser curvature situated at least 0.8 inches below the umbilical level, (2) considerable emaciation due to anorexia, (3) severe constipation due to the pronounced bend of the pylorus, and (4) symptoms of gastric retention such as distress immediately after meals when the patient is standing erect.

Surgical treatment has never been employed generally for this condition because none of the indicated methods are satisfactory. The stomach is not a fixed organ and it is difficult to find a structure to which it can be fixed. The author considers the pancreas a conveniently situated organ for such purpose. The operation he describes consists of placing four sutures in the following manner: three sutures are placed at intervals through the lesser curvature and the upper border of the pancreas; the fourth suture is placed in the prepyloric pouch of the curvature and through the rou-

liver When these sutures are tied the stomach is pulled up considerably

During the last 18 years the author has followed 74 patients on whom he has performed this operation This group is divided into two categories In the first category, 66 patients are exceedingly well pleased with the results All these patients are apparently well and can eat all sorts of food without symptoms The majority of them have gained an average of 20 pounds in weight, and one patient gained 55 pounds Roentgenographic check-up showed a "good" position of the stomach In the second category, the 8 remaining patients are classified as "neurotic" by the author In these patients the results have not been good and, in retrospect, they are considered poor candidates for surgery The author emphasizes that the operation should be undertaken only when the indications are very definite

HAROLD LAUFMAN, M D

The Fate of Patients Following Stomach Operations
(Das Schicksal des operierten Magens) FRITZ
HFESE *Deut Gesundheits*, 1949, 4 142

The late results of 237 operations on the stomach are analyzed and presented in statistical form Questionnaires sent out revealed that 21.5 per cent of the patients were dead, 34.6 per cent survived, and in 24.0 per cent of the cases the fate was unknown, 19.9 per cent of the questionnaires were ignored The material is tabulated in detail and summarized in the following table

	Per cent
Gastric carcinoma	18.2
Benign pyloric stenosis	36.3
Gastric ulcer	18.2
Duodenal ulcer	0.1
Penetrating and perforating ulcer	18.2
Men	85.0
Women	15.0
Under the age of 50	36.4
Over the age of 50	63.6
Hereditary history	36.4
Operative methods Gastroenterostomy	36.3
Billroth I	6.1
Billroth II	18.2
Polya-Reichel	18.2
Suturing	21.2
Complaints at present	75.6
No complaints at present	24.4
Ulcer at present	18.4
Gastritis at present	30.3
Carcinoma at present	3.3
Limited earning capacity	48.5
Unlimited earning capacity	51.5

Studies of gastric acidity revealed normal values in 42.4 per cent of cases, hyperacidity in 27.3 per cent, and hypoacidity to achylia in 30.3 per cent Further statistical analysis of the material is presented

The author concludes that in those patients operated upon for gastric carcinoma, only a certain prolongation of life can be anticipated, and hardly any permanent cures Of the remaining patients, in-

cluding those with complaints, only a few can be classed as unfit for work Attention is drawn to the use of a mathematic statistical method of study for avoiding subjective errors of observation

JOHN L. LINDQUIST, M D

Regional Hypertrophic Enteritis at the Ileocecal Bottleneck, Crohn's Disease (Entérite régionale hypertrophiante localisée au défilé iléo caecal, maladie de Crohn) G BROEHE, L DAUMERIE, and G RICKAERT *Acta gastroenter belg*, 1949, 12 158

The authors discuss the symptoms, the pathologic anatomy, and the treatment of terminal ileitis, and report one case of their own observation

The disease should be suspected when a patient presents a movable, sausage-shaped mass in the right iliac fossa, with or without subfebrile temperature, and shows any of the following symptoms attacks simulating occlusion of the bowel, acute crises of abdominal pain without fever, and abscesses in the right iliac fossa or at the cul de sac

The affection is often mistaken for chronic appendicitis, colitis, postoperative bands or adhesions, invagination, volvulus, mesenteric thrombosis, or intestinal tuberculosis

In the majority of cases, only roentgenologic examination makes it possible to clinch the diagnosis The findings include hypermotility, spasm of the ileocecal sphincter, dilatation of the ileum proximally to the affected area (megaileum), moderate to extreme narrowing of the lumen ("cord sign"), rigidity and irregularity of the intestinal wall, especially at its mesenteric aspect which shows indentations, spicules, and fissures

The pathologic anatomy shows extreme hypertrophy of the muscularis, chronic inflammation of the mucosa, small abscesses in the involved area, fissures, necroses, and sinuses into neighboring organs or in the abdominal wall

Treatment is surgical only (resection of the affected part of the ileum) Better results are obtained when resection is performed as early as possible in order to prevent complicating stenosis or abscess formation

WERNER M. SOLMITS, M D

The Development of Deep Duodenal Ulcer (Zur Entstehung des tiefen Ulcus duodeni) VICTOR
HOFFMANN *Chirurg*, 1949, 20 49

In studying many specimens of resected ulcer, the author has often found the ulcer process in a condition which presented a clue to its evolution He has found histologic evidence of ulceration occurring secondarily in a zone of infarction Opposite to callosus ulcer of the duodenum he has found an area in which the superficial layer of mucosa was preserved, but beneath which a process of degeneration in the submucosa, muscularis, and serosa was evident

Photomicrographs are presented showing a wedge-shaped zone of degeneration of the entire thickness of the duodenal wall with the point of the wedge directed toward the mucosa The sharply demarcated wedge of degeneration presents the histologic

SURGERY OF THE ABDOMEN

picture of an infarct. It cannot be said, however, that this infarct is a result of thrombotic closure of the vessel, since the broad side of the wedge lies immediately at the vessel barrier. The author is inclined to consider a functional disturbance of circulation (such as spasm), or interference as a result of arteriovenous anastomoses, as the cause of this degeneration.

Two facts stand out which permit the inference that duodenal ulcer is a result of circulatory disturbance: (1) the definite zone of degeneration beneath a preserved superficial layer, and (2) its localization to an area predisposed to ulcer.

JOHN L. LINDQUIST, M.D.

Treatment of Jejunal Ulcer: A Comparative Follow-Up Study. HENRY K. RANSOM. *Arch. Surg.*, 1949, 58: 684.

This study was made on a group of 81 patients treated surgically for postoperative jejunal ulcer at the University Hospital, Ann Arbor, Michigan, during the past 20 years. Operations performed for gastrojejunocolic fistula or for a malfunctioning or unnecessary gastroenterostomy opening, as well as those for recurrent duodenal ulcer following plastic procedures on the pylorus have been excluded intentionally.

The previous operation which had failed most often in these patients was (1) gastroenterostomy, (2) duodenal exclusion operation, (3) gastric resection, which in this series included 3 pylorotomies.

In the entire series of 81 patients there had been 106 operations, as listed in the following table:

	No. of operations
Gastroenterostomy	60
Devine exclusion	8
Gastric resection	7
Closure of acute perforation	7
Finsterer resection for exclusion	6
Pylorotomy	3
Excision of gastric ulcer	2
Closure of acute perforation and gastroenterostomy	2
Dismantling of gastroenterostomy mechanism	1
Gastroenterostomy and excision of duodenal ulcer	1
Vagotomy (abdominal)	1
Plastic to jejunal ulcer	1
Jejunojunostomy	1
Gastrostomy	1
Closure of gastrostomy	3
Unknown	106
Total	

Among the 9 gastric resections which failed, 2 small resections which were scarcely more than pylorotomies had been performed, in the remaining 7, one half or more of the stomach had been removed. In these 7 cases the reconstruction had been made by the posterior Polya method in 3, the anterior Polya method in 1 case, and the posterior Hofmeister method in 2 cases, all without enterostomy. The exclusion operation of Devine was done in 8 instances and Finsterer's resection for

exclusion in 7 additional ones. The total experience with exclusion operations at the University Hospital may be summarized briefly as follows: Data available on 22 cases of primary duodenal ulcer treated by the Finsterer type of resection for exclusion, 14 similar cases in which the Devine exclusion method was used, and 29 cases in which the Finsterer procedure was modified by "exenteration" of the antral mucosa. The results in these three groups are:

1. Finsterer—7 patients are well, 5 were benefited, and 10 are in poor condition.
2. Devine—2 patients are well, 3 were benefited, and 9 are in poor condition.
3. Finsterer with exenteration—25 patients are well, 1 patient was benefited, and 3 are in poor condition.

When treating a patient with jejunal ulcer, the operator must be governed considerably by the previous operative procedure, the condition of the patient, the technical difficulties present, and to a certain degree by his own preferences. In this series of patients there were 6 deaths, 1 of which occurred in the dismantling of a gastroenterostomy from peritonitis, 1 from intestinal obstruction in a similar procedure, 1 from hemorrhage, 1 from peritonitis due to the resection, 1 from pancreatitis and peritonitis following an antral excision, and 1 from inanition due to jejunostomy.

Of the 75 remaining patients, 52 are alive and 23 are dead. The causes of death in these 23 were:

	Cases
Recurrent ulcer	0
Reoperation for recurrence	5
Coronary thrombosis	3
Pneumonia	2
Hypertension and myocarditis	2
Cerebral hemorrhage	1
Accident	1

This article included a study of vagotomy, which was employed in 64 cases with the following results: good in 41 (64.1 per cent), fair in 17 (26.5 per cent) and poor in 6 (9.4 per cent).

In the definitive treatment of gastrojejunol ulcer following gastroenterostomy, the dismantling operations with restoration of the gastrointestinal tract to normal have proved unsatisfactory, and there would now seem to be few if any indications for their use. An adequate gastric resection, on the other hand, probably offers the greatest chance of cure. When recurrence follows a conventional or an exclusion gastrectomy, the status of the original resection should be carefully evaluated. If the antrum remains or if the resection was small, a resection that is adequate as judged by present day standards, is indicated. When recurrence is encountered in patients who already have been subjected to an acceptable resection, vagotomy affords a new and promising mode of treatment, whereas formerly, for this group of patients, only total or nearly complete gastrectomy remained.

SAMUEL J. FOGELSON, M.D.

Present Concepts in Ulcerative Colitis A W Morrow
Med J Australia, 1949, 1: 403

Ulcerative lesions of the large bowel are produced by many diseases, the best known are bacillary dysentery, tuberculosis, lymphogranuloma venereum, amebiasis, and uremia. However, in many cases, no etiologic factor can be determined and the disease has been variously named idiopathic ulcerative colitis, nonspecific ulcerative colitis, or thromboembolic colitis. Sir William Osler is said to have described the disease in 1875. The malady may be defined as a disease or group of diseases of unknown etiology, characterized clinically by diarrhea (bloody at some stage), crampy abdominal pain, fever, anorexia, anemia, asthenia, and weight loss, remissions and exacerbations are frequent and unpredictable, and during the active phase sigmoidoscopic examination usually shows an ulcerated mucosa.

Under etiology the author discusses the factors of infection, allergy, dietary and vitamin deficiency states, neurogenic and psychogenic concepts, and the enzymatic (lysozyme) theory. There is no one primary etiologic factor. Infection plays a large part in the clinical manifestations but it probably follows some other factor which alters mucosal resistance. Also local allergy may play a part and should be considered in the treatment. Emotional disturbances are undoubtedly concerned in exacerbations and relapses, and if they can be shown to be the causal factor in the production of excess lysozyme, then perhaps the disease may be regarded as primarily neurogenic.

Clinically, the disease has not changed through the years, but recently certain manifestations have been noted more often.

Crohn called attention to segmental, regional, and right-sided colitis in 1925. He states that in this subgroup the process begins in and is commonly limited to, a segment or segments of the proximal part of the colon. The characteristic history of the disease is a progressive march to the left, until by skip lesion or by continuity the whole colon from cecum to sigmoid may become interruptedly or continuously involved. The local signs and symptoms such as bloody diarrhea and straining are less severe, but constitutional symptoms such as fever, joint pains, and anorexia are more apparent. The condition is amenable to surgical short-circuiting procedures. Sigmoidoscopic examination may reveal a normal mucosa. Occasionally the terminal portion of the ileum is involved, in which instance the condition is usually grave.

It has been commonly believed that the disease is inevitably progressive from the rectum to the cecum, but evidence has suggested that in the majority of patients the disease attacks the colon either partially or completely during the initial episode and usually remains relatively stationary in distribution thereafter.

The extent of involvement as shown roentgenologically is not correlated directly with the type of onset, the duration of symptoms, or the clinical

severity of the disease. Roentgenologically, the colon may appear normal in a patient with clinical evidence of the disease, and occasionally the colon appears extensively involved in a patient with minimal clinical signs. Sigmoidoscopy and stool examination are essential in order to determine the pathological state of the bowel.

Undoubtedly, severe liver damage occurs in cases of extensive ulceration, but the incidence of liver disease is probably no higher than in some other diseases which cause chronic protein deficiency. This systemic effect of the disease should not be neglected by the clinician.

Malignant degeneration is an important complication of chronic ulcerative colitis. The incidence was 3.2 per cent in 871 cases at the Mayo Clinic and 2 per cent in 450 cases at the Lahey Clinic. Morrow re-emphasizes Cattell's point that the incidence of malignancy is high in children and that it may occur in patients who have been in remission for years, and in a colon which has been excluded by ileostomy. Undoubtedly, malignancy is much more frequent in the bowel of a patient with ulcerative colitis.

In treatment, the main objectives have not changed, they are control of the symptoms, arrest of the inflammatory lesion, and prevention of invalidism. There are no specific therapeutic measures. Reliance must be placed on palliative and supportive measures such as control of diarrhea by opium, papaverine, belladonna, bismuth and kaolin, correction of malnutrition, blood loss, and protein depletion, eradication of other foci of infection, and attention to the psychogenic factors. In addition to the general measures, varying methods are in use for the treatment of the inflammatory process in the colon. At present a chemotherapeutic and antibiotic approach, locally and parenterally, seems most successful. If the colon can be put at rest, the effect of the therapeutic combination used will be enhanced. Ileostomy will do this but it is permanent. The author gives two methods of placing the colon at physiologic rest, at least for a short period, to assist other therapeutic measures, they are total intravenous alimentation and medical ileostomy.

The author reports on 4 patients treated by total intravenous feeding, the period extending from 8 to 13 days. Various casein digests, glucose, saline solution and blood transfusions, parenteral liver extract, and vitamins were used. The total fluid intake was approximately 3 liters daily. Only sips of water were allowed by mouth. Within 48 hours, bowel actions ceased in 3 of the 4 patients, the fourth having one to two movements a day throughout the period. Fever subsided in 2 patients. One patient remained in remission after cessation of the therapy, the 3 others relapsed when oral feeding was started but their general condition was much better. The sigmoidoscopic examination showed no great improvement, in contrast to the clinical state. During this period there was no sensation of thirst,

SURGERY OF THE ABDOMEN

and the colicky abdominal pains ceased. Bowel actions occurred if anything additional to sips of water was taken by mouth.

In medical ileostomy the aim is to pass a Miller-Abbott tube to the terminal portion of the ileum and then to apply continuous suction. By these means, small bowel contents are prevented from entering the large bowel. Fluids of a high protein, high carbohydrate, and high vitamin content are given freely by mouth. The purpose is to supply adequate nutrition and at the same time to place the large bowel at rest. Frequent fluoroscopy is necessary to determine the location of the tip of the tube. This is sometimes distressing to a seriously ill patient. Considerable skill and constant attention are required to keep the tube in position and functioning. There is a constant tendency for the tube to pass into the colon, which is indicated by increase in the frequency of bowel movements or diarrhea and abdominal pain. Because of these factors the method may have to be abandoned in some cases. If position of the tube can be maintained, the results are gratifying. These two methods are helpful, and for the acutely ill patient who is rapidly deteriorating either method may be lifesaving.

EDWIN W. PASSARELLI, M.D.

Ulcerative Colitis. The Ileostomy Life E. E. DUN
Med J Australia, 1949, 1: 399

Experience has shown that ileostomy and colectomy are the most important surgical procedures for the treatment of nonspecific ulcerative colitis. Extensive initial operations are contraindicated because of the condition of the patients, therefore, ileostomy is employed both as a form of treatment per se and as a preliminary measure to colectomy.

In favorable cases, especially when diseased segments of bowel can be removed, it may be possible to restore alimentary continuity without relapse or deterioration. When there is heavy involvement of the rectum, especially when extensive perirectal suppuration and fistulas are present, such an artificial anus should not be made without consideration of the fact that subsequent closure might involve a great risk of relapse. Some patients will not regain health without complete excision of such chronic and intractable forms, it may be wise to allow prolonged periods to elapse between the stages of operation. Good management is of great importance.

There is a natural prejudice against an artificial anus of any type that is shared by doctors and patients alike. Some doctors have shrunk from surgical treatment because of misconceptions of the magnitude of the difficulties, dangers, and discomforts of ileostomy drainage.

The objections to ileostomy are stated as continued soiling with fluid feces, disturbances of the metabolism and nutrition, digestion of the skin, frequency of the formation of abscesses and fistulas, and the incidence of strictures of the colon due to

The author answers the objections as follows: Ileal discharge thickens postoperatively and is not as offensive as in colostomy drainage. No lasting disturbance of the metabolism occurs, as evidenced by many clinical observations including those in Japanese prison camps. Excoriation and redness of the skin are likely to occur if the skin is permitted to be continually moist, but the contents of a healthy ileum will not cause digestion of the tissues nor failure of wound healing. The author relates abscess formation and fistulas to errors of operative technique and particularly to the exteriorization of the diseased ileum. The scarring must be attributed to the severity of the disease itself, because in long standing, severe damage with extensive loss of mucosa scarring is inevitable and structure may take place.

Although the objections are not well grounded, ileostomy is an inconvenience. It has not been shown that temporary ileostomy will cure the disease at any stage and an apparent complete remission may be followed by relapse. The author suggests that the operation is indicated as the initial step in surgical treatment (a) when failure of medical treatment associated with grave deterioration has occurred in fulminating, acute, or chronic cases, and (b) when serious complications arise. The author uses Bargen's outline of complications (a) perforation, threatened or present, (b) repeated hemorrhages, (c) fistulas and sinuses associated with the colon or rectum, (d) stenosis and obstruction associated with extensive colitis, (e) polyposis (pseudopolyposis), and (f) carcinoma of the large bowel. The last is not infrequent in long standing ulcerative colitis with pseudopolypoid changes.

Preparation for ileostomy in the absence of dehydration, emergency consists in the correction of dehydration, chloride depletion, anemia, and hypoproteinemia by intravenous methods or high caloric, high protein, low residue diets and added vitamins.

For these sick patients, the initial operative procedure should be simple and of as short duration as possible. The author prefers a double-barrelled ileostomy through the right lower rectus for the reason that it will usually insure sufficient improvement for colectomy to be performed in a single stage, then the proximal limb of the ileum may be transferred to a similar site on the left side where it is brought out with the distal stump of colon.

The author stresses three points of technique as follows:

- 1 The long exploratory incision should be avoided except when there is a special indication, and the temptation to examine the friable colon should be resisted. The site of the incision is dictated mainly by comfort for the patient in wearing an ileostomy bag, which necessitates a stoma below the belt, away from the anterior superior iliac spine, the umbilicus, and the inguinal fold.
- 2 The site is of great importance in avoiding subsequent wound suppuration and fistula formation because the terminal ileum is frequently

volved in the disease process. The site selected should be at least from 12 to 18 inches from the ileocecal junction.

3 In fixation the selected loop is withdrawn and first the mesentery and then the bowel are divided. Soft flexible tubes of good internal bore are fixed in both limbs in a water-tight fashion. The two limbs with the contained tubes are so placed in the wound so as to allow a projection of about 1 inch of bowel, and the functioning stoma is placed below the other. It is necessary only to suture the ileal mesentery to the wound incision with an interstitial mattress suture through all layers of the abdominal wall and an avascular area of the mesentery. Abscesses and fistulas about the stoma usually arise from needle punctures in diseased ileum.

Postoperatively, the afferent tube is irrigated in the operating room to be sure it is open, the bowel is covered with vaseline gauze, and the wound is not disturbed from 7 to 9 days, when the tubes loosen. The skin is healed sufficiently for a bag to be applied. Morphine is valuable in the early stages. Fluids by mouth are permitted on the day of operation, and on the next day a soft, low residue diet with ample vitamins is started. This promotes an ileal discharge. Hiccup, abdominal pain, distention, and vomiting may accompany cessation of the drainage. Obstruction is most often due to roughage in the diet and this should be avoided in the first few weeks when the exteriorized bowel is edematous. Treatment may involve finger dilatation, irrigation of the obstructed loop, or Wangenstein suction to the ileum. Attention to fluid balance must be thorough because the discharge at this stage may be from 50 to 60 fluid ounces a day. Skin excoriation is usual at first, but this passes as the skin becomes inured to irritation; tannic acid jelly may be of help. When signs of active colitis and toxicity persist, colon lavage may help, occasional good results have been noted with sulfaguandine suspended in saline solution and with phthalylsulfathiazole.

The ileostomy stool following the compensatory changes is nonoffensive and alkaline in reaction. The stool thickens in a few weeks and is usually semifformed by 3 months. When the largest meal is in the evening, the discharge is most profuse in the early part of the night and there is relatively little in the mornings. The bags are usually emptied from 3 to 6 times daily. Those patients who cease to have rectal motions usually prefer to wash the colon instead of removing the debris at 1 or 2 week intervals. The essential features of a suitable bag are accurate fit and ease in emptying, it should also prevent soiling of the skin. With all types of bags, prolapse of the ileum may occur occasionally especially if the patient continues strenuous pursuits. A restriction of roughage is essential for a few weeks after the operation. The patient soon learns which foods cause an unfavorable reaction and most patients find no restrictions necessary after a few months.

The mortality rates are determined largely by the condition of the patients prior to operation and the range is therefore wide, varying from 3.8 per cent to 23 per cent in different series.

Early treatment by ileostomy is advocated by some surgeons before changes in the large bowel become irreversible so that eventual disconnection of the ileostomy may be practical. The author cites Lattell's criteria for closure: complete remission for at least 12 months, no ulceration on sigmoidoscopic examination, and x-ray evidence that the colon has a satisfactory lumen and some flexibility as shown by haustral markings. Relapse occurs frequently even under these favorable conditions so that closure of the ileostomy has only limited application. For the type of patient seeking surgical aid at present, colectomy is usually advisable, and some types require excision of the rectum as well. When the rectum shows apparent healing after colectomy, ileo-rectal or ileosigmoid anastomosis may restore continuity. The period of "dysfunctioning" of the rectum should be prolonged, restoration of continuity by the crushing clamp method is much safer than by suture.

The relief from distressing invalidism experienced by most of these patients gives them a cheerful mental attitude so that many find it possible to return to their normal occupations and to live a full life.

EDWIN W. PASSARELLI, M.D.

Ulcerative Colitis: Clinical Features, Diagnosis, and Treatment. GEOFFREY A. PENINGTON. *Med J Australia*, 1949, 1: 405.

The initial manifestations of ulcerative colitis are usually acute diarrhea, followed by the passing of blood-stained mucus in gradually increasing amount, mild fever, anorexia, and malaise. In other patients the onset is insidious, extending over a period of several weeks with the gradual development of uncontrolled diarrhea and ill health. In some instances, there is a history of recurrent attacks of diarrhea and normalcy extending over several weeks. A fulminating onset may occur.

The clinical features of ulcerative colitis are readily understood if the pathology and morbid anatomy are considered. There is a gross inflammatory reaction in the mucosa with actual destruction resulting in ulceration, which may extend deeply into the muscularis and actually cause perforation. The surviving mucosa is edematous and even inflamed. Infiltration of the whole thickness of the intestinal wall may be present with thickening, pericolic inflammation, adhesions to neighboring viscera, and the formation of abscesses and fistulas. Remote complications due to bacteremia or toxemia are common. Attempts at healing result in fibrosis with stenosis and shortening of the bowel and mesentery. The peristalsis is abnormal. Intestinal contents become abnormal, and blood, pus, and serous exudate are present. The bacterial flora is altered and recognized pathogenic organisms are often present. The personality of the patient is inevitably affected by the na-

SURGERY OF THE ABDOMEN

ture of the illness and the physiologic activity of the whole alimentary tract is upset.

The author directs particular attention to the personality, toxemia, and local and remote complications. That personality changes occur in these patients is undoubted, these changes occur to such a degree that there have been protagonists of the psychogenic causation of the disease. Immaturity, childishness, emotional instability, dependence, sensitiveness, over conscientiousness, fussiness, anxiety, and fear of failure, may be present singly or in combination. It is obvious that social, economic, or domestic difficulties cannot fail to have a profound effect on such individuals, and aggravation of existent lesions would be inevitable in greater or lesser degree. However, it remains to be proved that psychogenic factors actually cause ulcerative colitis. Many clinicians of repute have asserted that colon neurosis does not progress to ulcerative colitis.

Toxemia is always present and is manifested in intermittent fever, sweats, tachycardia, loss of weight, malaise, anorexia, headache, and lesions remote from the colon, namely, arthritis, ocular disease, renal lesions, thrombosis, inflammation of serous membranes, and splenomegaly.

Emaciation may be extreme, it is due not only to decreased caloric intake as a result of a poor appetite, but to the loss of blood and protein, disordered digestion, and increased catabolism from toxemia. Too often the caloric value of food has been wrongly reduced in order to obtain a diet with no residue. Severe hypochromic anemia and low serum protein content, especially the albumin fraction, are in some measure the result of toxemia, but they are aggravated by deficient diet and by persistent loss of blood and protein from the ulcers. Leucocytosis usually indicates the presence of complications. Avitaminosis is seen as the result of deficient diet aggravated by the use of sulfonamides and defective absorption from the intestinal mucosa.

The intestinal manifestations are disordered motility, toxemia, defective absorption, abnormal intestinal contents, and exudation from the mucosal lesions resulting in loss of appetite and even anorexia, vague abdominal discomfort, colicky lower abdominal pain, and diarrhea with small, liquid, offensive stools containing fecal material mixed with blood, pus, and varying amounts of mucus. Defecation is often painless but anal symptoms result from the frequent evacuations, and excoriation, hemorrhoids, and even prolapse of the mucosa may occur. Sleep is disturbed, vomiting is uncommon except in the fulminating cases, but when present may be well nigh uncontrollable. Abdominal tenderness is minimal over the course of the colon. The ileum may be felt as a firm, tender, cylindrical mass. Rectal examination provides little useful information, but must be done.

Local complications are the direct result of spreading of the inflammation, penetration of the mucosal barrier, or of attempts at repair. The mucosa be-

tween the ulcers is greatly swollen and may resemble polyps, both radiologically and sigmoidoscopically. Fibrosis may be present in adjacent areas, and the contraction resulting from healing of the ulcers causes narrowing of the lumen which is further augmented by the swollen mucosa, and may produce partial obstruction. An apparent stricture may be due principally to mucosal swelling, and, with remission of the disease, the lumen returns to approximately its normal diameter. Actual strictures, in addition to these pseudostrictures, do occur. Pericolic inflammation, adhesions, fixation of the colon, shortening of the mesentery and shortening of the colon develop in the uncontrolled disease. Abscess formation and fistulas are the direct result of extension from the intestine.

Carcinoma of the colon in association with ulcerative colitis is higher in frequency than in the general population. Whether there is any causal relationship between these diseases is a matter of conjecture. It is very important to exclude the presence of carcinoma in these patients.

Hemorrhage from the colon is present to some degree in every case. Ileostomy decreases this tendency, but does not obviate it. This is readily understood if the pathological picture of the lesions is considered. Severe hemorrhage with a fatal result is more likely to occur at a late stage of the illness. Hemorrhage may actually be the presenting symptom and may wrongly be attributed to hemorrhoids. The bleeding is in a large measure responsible for the severe hypochromic anemia found in ulcerative colitis.

Perforation of the colon and general peritonitis occur rather frequently in fulminating cases, perforations may be multiple. Ileostomy is part of the emergency treatment in such cases.

The remote complications result chiefly from toxemia and are not particularly characteristic of ulcerative colitis, polyarthritis is common, the pleura and pericardium may be the site of inflammatory reactions, endocarditis occurs. Septicemia may terminate the illness. Renal lesions producing the nephrotic syndrome and splenomegaly are due to the toxemia. The presence of hepatic damage may be partially responsible for the low blood proteins. Thrombophlebitis has occurred even after ileostomy. Ileostomy does not obviate the complications although the local lesions are spared from aggravation.

The course of the disease varies according to its severity and mode of onset. In fulminating illness, perforation is a frequent cause of death early in the disease. In less severe cases there is great variability in the natural history. Spontaneous remissions and relapses make assessment of therapeutic difficult. Fever may be very slight in spite of progressive deterioration both locally and generally. The complications may become the predominant clinical features. Prolonged remission of many years' duration may simulate a cure, but eventual relapse after 10 to 20 years shows the unpredictable course of the disease. Ileostomy and subsequent colectomy appear to be the most suitable means of attaining reasonable h-

in intractable cases—those showing progressive deterioration, lack of response to adequate medical treatment, or severe toxemia

The diagnosis of ulcerative colitis is made by exclusion of conditions resembling it and by recognition of its specific features. Colon neurosis must be excluded, it must be remembered that this may be superimposed or may result from an organic lesion. Chronic dysentery, protozoal and helminthic infestations may be difficult to differentiate, but a competent pathologist can usually provide positive evidence of the cause. Actinomycosis, tuberculosis, lymphogranuloma venereum, Crohn's disease, carcinoma, polyposis, hemorrhoids, diverticulitis, mercurial poisoning, uremia, and thyrotoxicosis can be excluded by careful history, thorough physical examination, and appropriate investigations. Granular proctocolitis (hemorrhagic proctitis) is probably the most difficult condition to differentiate from early ulcerative colitis. In this stage they may exactly resemble one another. The only certain method of differentiation is in the fact that granular proctitis does not progress to frank ulceration, is not accompanied by a profound general disturbance, and eventually resolves. Recurrences are seen but the patient never presents the general clinical picture found in ulcerative colitis.

Among the diagnostic procedures used in disorders of the rectum, sigmoidoscopy is the most important and should always be performed if digital examination shows no contraindication. The clinical history must include a social and personal history, occupational and environmental history, past and present, inquiry regarding dysenteric infection, protozoal or helminthic infestations and the administration of mercury.

Macroscopic and microscopic examination of feces is made for pus, mucus, and blood, microscopy involves a search for cells, ova, amoeba, cysts, and organisms. Cultures are necessary for pathogenic organisms. Frequent blood counts must be made. Serum protein levels give an indication of toxemia. Agglutination tests are performed if there is increased temperature, and blood culture may provide valuable information. Roentgenography of the colon by means of the barium enema is of great value in determining the extent of the lesions and in excluding carcinoma, polyposis, stricture, etc., but an accurate diagnosis of the state of the colon cannot be made from the x-ray picture alone. A drastic purge must never be given to a patient suspected of having colitis prior to this examination because of the real danger of precipitating a relapse. The examination alone causes some general and local disturbance. A fractional gastric analysis is of no diagnostic importance, but may help in management. Allergy tests should be performed if there is any reason to suspect an allergic factor. Mantoux, Kahn, or Wassermann tests and chest roentgenograms should be routine practices.

Chemotherapy is a means of combating infection in the lumen of the bowel and some attempt must be

made to destroy organisms actually in the wall. It is practically impossible to determine whether the organisms are susceptible to sulfonamides or penicillin, but there is reason to believe that toxemia is controlled in some measure by their use. There is preference for phthalylsulfathiazole and penicillin used simultaneously in full recommended dosage or larger. The patient must be kept at rest in bed and given sufficient fluids to overcome dehydration. In addition, the diet must be carefully arranged to provide a high caloric value (3,000 calories or more), high protein, high carbohydrate, high vitamin content, but little residue. The residue must be soft and not mechanically irritating. Vitamin supplements are given, especially vitamins A, B, C, and K. Increases in diet must be made gradually and with resumption of a more normal diet, care must be taken to avoid indigestible substances. Blood transfusion will correct the anemia, frequent small transfusions are preferable to infrequent large ones. The social, economic, and domestic difficulties must receive attention oftentimes by the psychiatrist. Symptomatic therapy by use of antispasmodics, sedatives, and adsorbents is necessary for control of pain, diarrhea, hiccup, malaise, headache, cramps, and disturbed sleep. The only surgical procedure that can be effective in affording some rest to the damaged colon is ileostomy. The improvement in the patient's general condition after operation is remarkable. Operation should not be a last resort in treatment of a moribund patient. If there is progression of the lesion, continued loss of weight and strength, uncontrollable toxemia and a certain diagnosis of ulcerative colitis, ileostomy should be performed without delay. Colectomy must follow. Only if the rectum is not involved is it reasonable to consider later anastomosis of the ileum and rectum. Lesions remote from the colon must be treated as necessary, but colectomy is the only sure means of obviating such complications.

EDWIN W. PASSARELLI, M.D.

Discussion on Hirschsprung's Disease T. TWIST, INGTON HIGGINS, F. DOUGLAS STEPHENS, MARTIN BODIAN, and RICHARD MEYER. *Proc. R. Soc. M., Lond.*, 1940, 42, 221.

In the reported discussion, the authors reach similar conclusions on Hirschsprung's disease.

Hirschsprung's disease, or megacolon, may be classified as

1. Acquired (or "pseudo") Hirschsprung's disease in which comparatively simple treatment affords a good prognosis.

2. True Hirschsprung's disease of a mild type, in which the distal segment is relatively short and wide. Simple treatment by spinal anesthetics or other conservative measures may give relief, and the prognosis is relatively good.

3. True Hirschsprung's disease of a severe type, in which the distal segment is long and narrow. The clinical picture is intractable and relentless from birth. Treatment by spinal anesthesia and symp-

thectomy does not afford effective relief, and the only alternative is surgical resection of the distal obstructive segment, upon which it has been learned to focus attention rather than on the dilated proximal loop of bowel. Removal of the dilated bowel will not remove the obstruction and the new proximal loop will undergo identical dilatation. It seems that the crux of the matter must lie in the distal segment in the severe type of the disease, and this etiologic factor must be removed.

SAMUEL J. FOGELSON, M.D.

Emetine and Appendicitis (Emetin und Appendicitis) EDUARD MELCHIOR. *Helvet. chir. acta*, 1949, 16: 126

The author's report, from the Chirurgischen Klinik des Numune Hastanesi, Ankara, is based on the experiences of the author in the use of emetine as a supportive measure following surgery for acute appendicitis when profuse generalized purulent peritonitis is encountered. The author states that cases in which there was a stormy postoperative course were controlled quite rapidly when the patient was given emetine. Several case histories are presented in support of this thesis. It would appear from the evidence presented that the administration of this drug was followed almost invariably by a remarkable diminution in fever, leucocytosis, and other toxic manifestations. The drug was used also in a number of cases after drainage of an appendiceal abscess. No evidence is presented to indicate that these patients were afflicted with amebiasis, although this possibility is discussed. The favorable effect of emetine is considered to be due not so much to its bactericidal action as to the fact that it is "antitoxic."

HAROLD LAUFMAN, M.D.

Volvulus of the Sigmoid Loop (Volvulus del asa sigmoidea) ALFREDO PIERINI. *Dia. med.*, B. Air, 1949, 21: 526

The author reports the results of his observations on 11 men and 7 women suffering from volvulus of the sigmoid.

Torsion of the mesosigmoid causes occlusion of the corresponding part of the gut, and strangulation of the blood vessels and nerves in the mesosigmoid. Volvulus occurs with greatest frequency in the fourth, fifth, and sixth decades of life. Its predominance in the male sex is more apparent than real, because in women a spontaneous detorsion is facilitated by the wider pelvis.

A redundant or an abnormally long sigmoid or megasigmoid is a predisposing factor. The condition may be of a congenital or acquired nature. Congenital abnormalities of the mesocolon, such as an unusually large formation, and abnormalities caused by mesosigmoiditis, adhesions, constipation, diarrhea, exclusive vegetarian diet, or the habitual use of laxatives may predispose to a volvulus of the sigmoid.

Among the determining factors, the following must be mentioned: sudden contraction of the

abdominal wall, brisk movements of the body, hyperperistalsis caused by cathartics or food, and rotation of the body transmitted to the distended sigmoid.

The torsion may be partial (less than 360 degrees) or total (360 degrees or more). Acute, chronic, and recurrent types may be distinguished.

Röntgenologic studies and rectosigmoidoscopy are indispensable in arriving at a diagnosis of the condition.

Conservative treatment, consisting of enemas administered in the knee-chest position, can be employed only in exceptional cases.

Surgical disengagement of the volvulus, with or without sigmoidopexy, does not prevent recurrences if a megasigmoid is present. Enteroanastomosis between the transverse colon and the sigmoid, or between the sigmoid and the cecum, is an unreliable method. A one-stage colectomy with an end-to-end anastomosis is the method of choice if the patient is not very old and his general condition is good; otherwise a two-stage colon resection, according to the Paul-Mikulicz technique, is recommended by the author. The spur is crushed 10 to 15 days after the second stage of the operation.

JOSEPH K. NARAT, M.D.

Critical and Experimental Studies of Sutures of the Colon in Dogs (Etude critique et expérimentale des sutures coliques chez le chien) D. GEROTA, K. PAMBUCCIAN, and F. SCOBATU. *Acta gastroenter. belg.*, 1949, 12: 81

The authors report the histologic findings following sutures of the colon in a series of 45 dogs. The animals were divided into three groups. In the first group of dogs, total transverse resection and end-to-end anastomosis was done. Catgut (No. 00) was used for the mucosa, and linen thread for the serosa. In the second group, linen was used for both layers. In the third group, the same technique was applied, but in addition the anus was closed by linen sutures for several days in order to test the solidity of the sutures in the colon.

The authors arrive at the following conclusions: although the same stages of healing are observed in sutures of the colon as in sutures of the stomach and duodenum, regeneration is slower and there is more likelihood of complications. This is probably due to the consistency and the bacterial contamination of the feces.

The fibrinous exudate of the peritoneum following the operation plays an important role in the prevention of bacterial invasion from the intestine; in addition, it forms a base for the development of scar tissue.

Continuous suture is not inferior to separate sutures, however, with separate sutures, a more exact fitting of the wound edges is assured. Infections and ulcerations are more apt to occur when linen is used in place of catgut for the mucosa. Voluminous knots should be avoided as they present an obstacle to the elimination of the threads.

WERNER M. SOLMITZ, M.D.

The Treatment of Carcinoma of the Rectum with Special Reference to the Preservation of the Sphincter Mechanism ROBERT MAILER. *Edinburgh M J*, 1949, 56 13

After reviewing the literature on carcinoma of the rectum, the author analyzes 19 cases of carcinoma of the rectum observed during the past 3 years. These patients were treated by "resection with restoration of continuity." The operations performed on these patients were divided into five groups (1) resection and primary anastomosis entirely from above, 11 cases, (2) abdominosacral resection with anastomosis, 3 cases, (3) abdominosacral mobilization with Hochenegg "pull-through," 3 cases, (4) sacral "cuff" resection with anastomosis, 1 case, (5) pre-anal resection and anastomosis, 1 case.

In the first group of 11 patients there was one death, and all but one (or 9) of the remaining patients have remained well to date with perfect sphincter control. Groups 2 and 3 comprised 6 patients, one of whom died, the remaining 5 developed fistulas and posterior space infection, and convalescence was prolonged. Two of the patients had local recurrence within 1 year of the operation and in both of these patients sphincter control was imperfect. Another patient had necrosis of the lower segment of the sigmoid, and 2 more developed severe stricture at the line of anastomosis. Thus, none of the patients in these groups obtained good results. The limited number of patients in groups 4 and 5, and the short period of observation hardly permits any significant conclusion from this material.

SAMUEL J. FOGELSON, M.D.

Advantages of End-To-End Anastomoses with Separate Sutures in Surgery of the Gastrointestinal Tract (Avantages des anastomoses à points séparés terminoterminales en chirurgie digestive) A. SAMAIN. *Acta chir. belg.*, 1949, No 1 25

The author discusses the advantages of separate over continuous suture and of end-to-end over end-to-side anastomosis in surgery of the gastrointestinal tract. Separate sutures are preferable because, (1) by not disturbing the vascularization an optimal blood supply is maintained and necroses of the intestinal wall is avoided, (2) by sparing the longitudinal and transverse muscles normal peristalsis is assured, whereas, by continuous suture the motility of the smooth muscles may be impeded and may lead to postoperative complications, and (3) non-absorbable suture material can be used with greater safety in separate sutures than in continuous suture. If a single linen suture is not tolerated and is eliminated, no harm is done, whereas, in continuous sutures, giving of the suture may lead to disaster. The author uses linen thread only in all resections.

End-to-end anastomosis permits better motility and prevents the formation of a cul-de-sac which may give rise to stasis and sinuses. Moreover, it is simpler from the technical point of view and goes farther in restoring the normal anatomic structure of the intestine.

WERNER M. SOLMITZ, M.D.

Continuous Suction Drainage JOHN R. PAINE. *J. Am. M. Ass.*, 1949, 140 149

Internists first developed the duodenal suction tube for diagnostic purposes. This work was started in the late nineteenth century. In 1921 Levin, of New Orleans, developed the smooth-tipped tube that could be passed through the nares and tolerated for a long period of time by the patient.

Wangensteen's contribution was antedated by sporadic reports of the use of such tubes for treatment by Westermann in 1910, Kappis in 1911, Kanavel in 1916, and Matas in 1924.

Ward, of San Francisco, described the use of continuous gastric or duodenal suction through a Jutte tube in the treatment of general peritonitis, postoperative ileus, intestinal obstruction, and acute gastric dilatation.

Wangensteen was not aware of Ward's work in 1931. About this time a man entered his ward with peritonitis of 42 hours duration from a perforation of the stomach. The perforation was closed surgically, and a catheter inserted through the anterior wall of the stomach. The resident and intern were assigned the task of keeping the stomach empty if possible, by constant suction. By morning they had improvised what is known now as "a suction set." This consisted of the familiar two bottles, connecting tubes, with one bottle draining water into a lower one and producing a negative pressure in the upper bottle.

Wangensteen speculated on the use of this principle in the treatment of mechanical bowel obstruction and subsequently treated 4 patients with the use of a duodenal tube and constant suction. In 3 of the 4 cases the results were remarkably good. He reported this in December, 1931 at the Western Surgical Association in Denver, and then returned to make a more thorough clinical study of the principles involved.

The chief significance of Wangenstein's contribution lies in the fact that it marks the beginning of a downward trend in the mortality rate of patients with intestinal obstruction. The mortality rate which had varied from 30 to 50 per cent dropped to about 15 per cent. The advent of the use of continuous indwelling suction marked the beginning of a new chapter in the understanding of the pathologic physiology of intestinal obstruction, and in the treatment of patients with all varieties of this condition.

FREDERICK C. HOEBEL, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Use of Portacaval Anastomosis in Portal Cirrhosis A. C. PATTERSON. *Arch. Surg.*, 1949, 58 590

Fourteen patients with portal cirrhosis, presenting either ascites or hemorrhage from esophageal varices, were operated on, and an end-to-side portal vein inferior vena cava anastomosis was accomplished in 10 cases. In 4 cases anastomosis was not feasible for various reasons. There was 1 postoperative death in the series of 10 portacaval anasto-

moses as a result of postoperative hemorrhage. All patients had been on medical management for prolonged periods.

On the basis of this series there are 3 operative findings that seem to be significant in the prognostication of the ultimate result. These are the size of the spleen, the height of the pressure in the portal vein, and the difference in the degree of pressure between the portal vein and the inferior vena cava.

The results in the group presenting massive hemorrhage from esophageal varices have been particularly gratifying, since no subsequent massive hemorrhages have occurred. Assessment of the group presenting ascites is more complex, mainly because of the multiple factors involved in the production of the ascites. In only 1 case was the ascites immediately controlled after operation. In others there was no improvement whatsoever for several months and then a gradual decrease of the ascites. One fact seems to be developing, that assessment of the end result cannot be made immediately.

Many preoperative and postoperative liver function tests have been made in all of these cases. These tests show no decrease in the functional status of the liver following portacaval anastomosis.

Primary Carcinoma of the Liver: 25 Year Study

G. F. STRONG, H. H. PITTS, and J. G. MCPHREE
Ann. Int. M., 1949, 30: 791

The authors discuss 43 new cases of primary carcinoma of the liver which, when added to the 12 cases previously reported by them, constitute 55 cases, i.e., 35 Chinese males, 2 Japanese males, 17 white males, and 1 white female. The tumors consisted of 41 hepatomas and 14 cholangiomas. The liver fluke was found in 4 of the Chinese patients. The incidence in whites was 0.26 per cent, more than double the previous incidence, and the incidence among the Chinese was 5.4 per cent.

Primary carcinoma is one of the most rapidly fatal of all malignant neoplasms. It matters little whether the tumor is hepatoma or cholangioma as far as prognosis is concerned. For orientals, the average age at death from hepatoma is 40.5 years, and for whites, 66 years, the average age at death from cholangiomas is 51.4 years for the former and 59.7 years for the latter.

The symptoms of primary carcinoma of the liver are those of a rapidly progressive cirrhosis, coupled with cachexia, weakness, and weight loss. The whole picture of cirrhosis is foreshortened and the portal obstruction leads to early ascites. In the authors' patients, pain, anorexia, weakness, and dyspnea were prominent symptoms.

The physical signs were of greater importance in diagnosis. The most common sign was ascites (31 cases), and hepatomegaly was present in 22 cases. The liver is enlarged and fixed early in the disease, with the result that the right diaphragm is elevated and shows diminished respiratory movement. Jaundice was present in 10 cases.

Primary carcinoma of the liver is of two types: (1) hepatoma arising from liver cells and (2) cholangioma arising from bile duct epithelium. There appears to be much greater pleomorphism and polymorphism of the cells in the hepatomas. The major distinction in the two types is the abortive attempt at bile duct formation and the relatively smaller size of the tumor cells in general in the cholangiomas. There is little question as to the relationship of cirrhosis to primary cancer of the liver, and some observers question the authenticity of a diagnosis of primary cancer of the liver in the absence of cirrhosis.

EARL O. LATIMER, M.D.

A Case of Gall Bladder Tuberculosis

GUSTAF ELFVING *Ann. chir. gyn. fenn.*, 1949, 38: 80

The author was able to find in the literature reports of only 25 cases of tuberculosis of the gall bladder. He presents the case of a woman 63 years of age who had no family history of tuberculosis. The patient suddenly became ill before Christmas of 1947 with symptoms of intestinal obstruction. At this time a small tumor was discovered in the right abdomen. The tumor slowly increased in size. The liver was enlarged 3 fingers breadth below the costal margin. X-ray examination of the chest revealed a faint shadow and calcification in the apex of the right lung. Gastrointestinal examination revealed the tumor to be to the right of the stomach and duodenum and above the hepatic flexure of the colon. Pyelography revealed the tumor to be independent of the kidney, and the left kidney could not be demonstrated.

A cholecystectomy was performed. The gall bladder was found to be greatly enlarged and inflamed, and was filled with small stones. The gall bladder wall was 5 mm thick. Histologic examination demonstrated extensive areas of necrosis in the mucosa nearly 1500 μ in width. In the layer beneath the epithelium was a round focus about 1000 μ in diameter. The core of the necrotic area was full of blood and cells that had undergone great degenerative changes. There were numerous giant cells in this area, and an infiltration of small cells and abundant connective tissue. Apparently tubercle bacilli were not demonstrated.

There is little difference between the symptoms of tuberculous cholecystitis and chronic gall bladder disease. Obstipation and a slight fever is not unusual. A palpable mass is not uncommon. In one-half the cases reported in the literature, gallstones were present. With the exception of patients who died ofiliary tuberculosis, and of one other patient, all were middle-aged women.

Gall Bladder Disease Among Filipinos, with a Report on Ascariasis of the Biliary Tract

F. E. QUIVEL and R. I. ALFONSO *Philippine J. Surg.*, 1949, 4: 22

The authors analyze the incidence, symptoms, and the pathologic findings in 100 cases of gall-bladder

disease occurring in Filipino patients treated surgically during the first 3 postwar years. The authors speculate that a general state of malnutrition in the environs of Luzon immediately following the Japanese surrender might have been a contributing factor favoring bile stone formation, since the incidence of gall-bladder disease decreased significantly with an amelioration of widespread starvation.

The authors present the remarkable finding of the presence of *ascaris lumbricoides* in 15 of the 100 cases. No other parasites were found. Two ascarides were found in the gall bladder in one case, in the remaining cases the worms, varying in number from one to eight, were found in the common bile duct, frequently in association with calculi.

In discussing ascariasis of the biliary passages the authors point out that there is no other entrance for the parasites than through the ampulla of Vater, and it is their impression that the worms cannot penetrate a normal sphincter. In cases in which the sphincter has been dilated by the passage of a stone, it is possible that the ascaris may roam freely to and from the duodenum, occasionally becoming entrapped in the upper levels in a milieu unsatisfying to its monosaccharide requirements and, as a result, vermicidal. The mere presence of the parasites in the common duct probably does not produce any special symptoms, even of obstruction. However, in the remote recesses of the biliary tree the dead worms acting as foreign bodies (or because of the bacteria they have transported from the duodenum) may start inflammatory processes in the bile passages or in the liver substance proper.

WAYNE CAMERON, M D

On Acute Pancreatic Affections Following Gastric Resections for Ulcer or Cancer, and the Possibilities of Avoiding them. ERIK MILBOURN *Acta chir scand*, 1949, 98 1

Acute pancreatic affection (the author avoids the term "acute pancreatitis") and pancreatic fistulas are not uncommon postoperative complications of gastric resections for ulcer or carcinoma. In a series of 147 gastric resections, tests of the postoperative urinary diastase by the Wohlgemuth procedure showed the presence of involvement pathologically of the pancreas in at least 10 per cent of the cases. In 6 cases the pancreatic affection was subclinical and was manifested only as a transient increased diastasuria, in 2 cases moderate clinical symptoms were observed, in 5 cases severe symptoms were present, and in 2 of these acute pancreatic affection was the cause of death.

The etiology of acute pancreatic affections following gastric resection is not uniform. Possible factors are (1) mechanical injury to the pancreatic tissue from the mildest (such as gentle) traction to the most severe, entailing breaks in the viscous, (2) vascular injuries, particularly those involving the superior or inferior pancreaticoduodenal and splenic arteries, (3) stagnation of the duodenal contents, possibly with regurgitation of bile into the pancre-

atic duct system, and (4) spasm of the muscles about the pancreatic duct orifices. A fifth factor, injury to the pancreatic ducts, is considered particularly important by the author.

The lesser pancreatic duct (Santorini) is especially exposed to possible damage during mobilization of the duodenum. If the duct of Santorini is the sole or main efferent channel of the pancreatic parenchyma, which it is in about 10 per cent of cases, the consequences of duct injury or of ligation during duodenal mobilization may prove to be deleterious to the patient.

It is the author's contention, therefore, that in duodenal ulcers the mobilization always be effected with an open duodenal stump in order that the surgeon may definitely determine the position of the greater and lesser duodenal papillas by palpation. Frequently the lesser papilla may be difficult or impossible to palpate. It is absent in 4 per cent of cases, and in spite of this the duct of Santorini may be well developed. In such cases care must be taken not to detach the duodenum from pancreatic tissue nearer than 3 cm adjacent to the greater papilla, especially in a ventral direction where the duct of Santorini usually opens into the duodenum.

When, during an operation, it becomes evident that a pancreatic duct has been injured, the type of pancreatic duct system (and the implications so far as ligation of the duct is concerned) can be determined by retrograde injection of methylene blue into the pancreatic portion of the duct or by the use of contrast media and the x-ray. With knowledge of the duct anatomy so obtained the measures taken by the surgeon in an individual case will be more adequate.

WAYNE CAMERON, M D

Indications and Results of Splenectomy. WARREN H. COLE, LEROY WALTER, and LOUIS R. LIMARZI *Ann Surg*, 1949, 129 702

The normal spleen contains the largest collection of lymphoid tissue in the body, and the bulk of the reticuloendothelial cells. It is intimately concerned with destruction of the red blood cells (almost one trillion per day) and potentially concerned with blood formation, although the physiologic mechanism involved in these splenic functions is not known. In fetal life, the spleen is active in the formation of all types of blood cells and can revert to this function upon demand at any period of life. In the adult this activity is limited to the production of lymphocytes and monocytes. By the reticuloendothelium of the spleen, the hemoglobin from worn-out erythrocytes is converted into bilirubin for passage to the liver. Much of the iron in the body is stored in the spleen, where it is available for the elaboration of hemoglobin and the formation of new red blood cells. The spleen, by virtue of its spongy network of pulp elements, serves as a controllable blood reservoir. The spleen exerts an inhibitory action on the hemopoietic function of the bone marrow, as evidenced by the almost constant occurrence of thrombocytosis and leucocytosis following splenectomy.

Most of the abnormal functions of the spleen are related to overactivity of one or more of the normal functions, thus giving rise to the term "hypersplensism." The functions most often becoming abnormal or overactive are the inhibiting effect on the bone marrow and the increase in fragility of the red blood cells. If the inhibition on the bone marrow affects platelet formation, thrombocytopenic purpura is produced. In hemolytic anemia the fragility of the erythrocytes, particularly the spherocyte, is increased, thus giving rise to sufficient erythrocytic destruction to produce anemia and jaundice, the latter from increased formation of bilirubin from the hemoglobin of destroyed red cells. If the bone marrow inhibition is limited to formation of neutrophils, the disease is known as splenic neutropenia. Various combinations of these abnormalities are encountered. When all three are present, the disease is designated as panhematocytopenia. In Banti's disease and in Felty's disease the inhibition of granulocytic maturation is also present, although in these diseases other abnormal features are encountered. The cellular elements of the blood may be formed in excess by the spleen. When the white cells are involved, one of the types of leucemia will result.

Leucocytosis and thrombocytosis regularly follow splenectomy. These changes reach a peak in 6 to 14 days and then slowly revert to normal. There is also a temporary slight increase in the erythrocyte count. The platelets may increase from a normal figure varying between 200,000 and 400,000 to 1,500,000. If the increase approaches the last figure named, it is desirable to give an anticoagulant such as heparin because thrombosis (venous) and emboli (pulmonic) are so apt to develop.

1 *Hemolytic jaundice* There are two types of hemolytic jaundice, namely, congenital (familial) and acquired. Because the results of splenectomy in the acquired type are so unsatisfactory, it is essential to differentiate between these two types. In the congenital type, several members of a family may be affected and the condition may be traced back through several generations. In the average case there is little interference with the well-being of the patient except for a marked yellow coloration of the skin and sclera, and a slight anemia. Symptoms are occasionally not noted until adult life. Splenomegaly, jaundice, anemia, microspherocytosis, and increased fragility of the red cells in hypotonic salt solution are prominent manifestations of congenital familial jaundice. Reticulocytosis and increased urobilinogenuria are usually noted. The spleen is usually greatly enlarged, and one-half to two-thirds of the patients have gall stones. The bone marrow study cannot be considered diagnostic.

In less than 50 per cent of the cases splenectomy will cure an acquired hemolytic anemia, but without affecting the underlying primary condition, such as leucemia, Hodgkin's disease, etc.

2 *Thrombocytopenic purpura* of the primary type responds to splenectomy, but the operation is of

little or no value in the secondary or symptomatic type. Marked enlargement of the spleen speaks against primary thrombocytopenic purpura. Bone marrow examination is diagnostic and will reveal a marked increase in the number of immature megakaryocytes without platelet production. The number of megakaryocytes in the bone marrow is such a reliable indication of true thrombocytopenic purpura that it may be used as an index of prognosis following splenectomy.

The authors are convinced that severe hemorrhage is a strong indication for immediate operation and not a contraindication. Huge quantities of blood may be required, and if shock is present intra-arterial transfusions may be indicated.

3 *Banti's disease* The authors believe splenectomy may have a curative, but most often remedial, effect on the disease in early cases. In the advanced cases the mortality rate is so high (5 of 13 cases in their series) that it outweighs by a large margin any benefit produced by splenectomy.

4 *Thrombosis or anomalous obstruction of the splenic vein* There is controversy as to whether or not this is a manifestation of Banti's disease. The authors have no final opinion as to the proper classification of this lesion. They are strongly of the opinion that splenectomy in the early stages of splenic vein obstruction should be curative, but equally convinced that splenectomy in early Banti's disease will by no means be curative in all cases.

5 *Felty's disease* Regardless of whether this is a separate entity, the authors recommend splenectomy in patients falling in the classification. At least temporary improvement was observed in 3 of 5 patients so classified.

6 *Splenic neutropenia* Results of splenectomy will be very good if the bone marrow shows a normal or increased number of normally developing granulocytes.

7 *Primary splenic panhematocytopenia* This, like splenic neutropenia, is a rare disease. It responds well to splenectomy.

8 *Rupture of the spleen* is, of course, an indication for splenectomy.

9 *Cysts, primary tumors and abscesses* are fairly definite indications for splenectomy.

The authors mention miscellaneous indications for splenectomy, such as Gaucher's disease, and massive resection of the stomach when it simplifies the procedure. Ptosis is occasionally an indication, as is splenomegaly with symptoms due to malaria, but only if the malaria has been eradicated, or to eradicate the site of malarial organisms giving rise to recurrent attacks.

Pernicious anemia, Hodgkin's disease, leucemia, and polycythemia are diseases in which splenectomy is contraindicated. This is true also for agnogenic myeloid metaplasia. Acute enlargement of the spleen in certain acute infections is a contraindication for splenectomy, also, enlargement due to such parasites, as encountered in trichinosis, filariasis, kala-azar, and distomiasis constitute contraindications,

although splenectomy in echinococcus disease may occasionally be justified. There is no justification for splenectomy in patients with metastases of malignant tumors.

The authors have adopted an incision that starts at the ensiform cartilage, proceeds downward and across the rectus muscle and thence laterally, parallel to the costal margin. The twelfth intercostal nerve is preserved and the eleventh is sacrificed. They frequently perform a preliminary ligation of the splenic artery before proceeding with removal of the spleen. The artery can be secured through an opening in the gastrohepatic omentum, but they prefer to ligate it at the superior border of the pancreas where it is found readily after incision through the thin posterior peritoneum. When the artery is large, as it will be if the spleen is large, exposure of the vessel will be most readily obtained. The fascia is closed with nonabsorbable suture material.

The authors discuss in detail their results from splenectomy.

EARL O. LATIMER, M.D.

The Value of Splenectomy in Splenomegalies Caused by Malaria (La valeur de la splénectomie dans les splénomégaties d'origine paludéenne) KAZIM ISMAIL GÜRKAN and BÜLENT TARCAN. *J. internat. chir.*, Brux., 1949, 9, 77.

The authors observed a great number of splenomegalies of malarial origin in Turkey, corresponding to the high incidence of malaria in this country. They differentiate three types: (1) those combined with liver cirrhosis, (2) those presenting the syndrome of Banti, and (3) those involving the portal circulation.

In a number of cases, there was no previous history of malaria, nor could the plasmodium be isolated from the blood. However, typical malaria attacks and the presence of the plasmodium in the blood after splenectomy proved the malarial origin of the splenomegaly in some of these cases.

The blood picture frequently resembled that of Banti's disease. It showed leucopenia, lymphocytosis, and anemia. In these cases splenectomy was the treatment of choice. The blood picture gradually returned to normal. Furthermore, the operation exerted a beneficial effect on the liver. Beginning cirrhosis was arrested, and the danger of hypertension in the portal system with all its sequelae was removed. Finally, degenerative processes like infantilism and retarded puberty cleared up after the operation.

However, splenectomy in these cases is not without great risks and the postoperative mortality is high. (No figures were given by the authors.) Retraction of the pedicle, excessive venous vascularization, and great friability of the organ make the intervention technically difficult. Thrombophlebitis of the venae liliacae occurred frequently after the operation. The average weight of the removed spleen was between 1 and 1.5 kgm.

In the preoperative and postoperative management, sulfonamides are strictly contraindicated be-

cause of the danger of agranulocytosis. Penicillin produces a beneficial effect. Heparin and blood transfusions were used frequently.

WERNER M. SOLMITZ, M.D.

Combined Splenectomy and Portacaval Shunts in Portal Hypertension LOUIS M. ROTHSCHILD. *J. Am. M. Ass.*, 1949, 140, 282.

The experience at the Spleen Clinic of the Columbia Presbyterian Hospital, New York, in 58 cases of portal hypertension is presented. The importance of the obstructive factor is stressed. The ultimate prognosis and selection of the type of surgical therapy depend on the following factors: (1) the nature of the obstructive factor, (2) its location, (3) the degree of portal hypertension, and (4) the efficiency of the collateral circulation.

Patients with intrahepatic block, that is, the cirrhotic patients, require the greatest exercise of judgment in timing before operation is contemplated because of their depleted state. In the noncirrhotic patients, the anemia associated with the congestive splenomegaly or from preceding hematemesis usually requires transfusion.

The author is convinced that splenectomy should always form the basic part of every surgical procedure, i.e., splenectomy with or without portacaval shunt rather than portacaval shunt alone. It is believed that the spleen in congestive splenomegaly exercises an inhibitory effect on blood formation. After splenectomy alone, there is usually a prompt rise of the granulocytes and thrombocytes to normal or greater levels. The erythrocytic rise is a slower process. Furthermore, the enlarged spleen in this disease probably carries some 40 per cent of the total portal blood flow, and its removal minimizes the sudden thrust of a large volume of blood on the overburdened esophageal varices.

With a block in the splenic vein close to the hilum of the spleen, splenectomy alone will suffice and a recurrence of hematemesis will be rare. When the block is at any point in the portal bed closer to the liver (that is, from the entry of the inferior mesenteric vein to the liver itself), a more radical operation must be considered. Experience has shown that in cases with hematemesis in which the block is proximal to the inferior mesenteric vein, bleeding will invariably recur if splenectomy alone is done, and the eventual rate of mortality will approach 100 per cent.

Practically all of the patients seen in the past 2 years have been treated by the suture method with preservation of the kidney and the use of the larger veins in the portal bed. The choice of portacaval shunt may be one of two main forms, the splenorenal shunts or the portal vein to inferior vena cava anastomosis. The splenorenal diversion is used in most of the cases with an extrahepatic block. The reason in these cases is predominantly in the portal vein which precludes the possibility of the Eck fistula. The Eck fistula, if used at all, should be reserved principally for patients with cirrhosis.

SURGERY OF THE ABDOMEN

The following outline is a résumé of all the various combinations of operations utilized in this series of cases

- 1 Splenectomy, left nephrectomy, splenic vein to left renal vein
 - a End-to-end, vitallium tube
 - b End-to-end, by suture
- 2 Splenectomy, no nephrectomy, splenic vein to left renal vein, end-to-side, by suture
- 3 No splenectomy (Eck fistula), portal vein to inferior vena cava
 - a End-to-side, vitallium tube
 - b End-to-side, by suture
- 4 Postsplenectomy
 - a Superior mesenteric vein to inferior vena cava, end-to-side, by suture
 - b Inferior mesenteric vein to left renal vein, end-to-side, by suture
 - c Splenic vein to inferior vena cava, end-to-side, by suture
 - d Inferior mesenteric vein to inferior vena cava, end-to-side by suture
- (1) Splenic vein to left renal vein, end to-end, by tube
- (2) Inferior mesenteric to left renal vein, end-to-end, by suture (double shunt at bifurcation to left renal vein)

The hospital mortality rate in the cases of cirrhosis of the liver was 21.4 per cent and in the non-cirrhotic group 12.5 per cent. The long term follow-up for the two groups shows a slightly higher death rate for the cirrhotic patients.

The author's experience is in accord with that of Linton who said that a surgeon should not attempt splenectomy in a case of portal hypertension without preparation to do a portacaval shunt, since this may be the only opportunity to construct a satisfactory shunt.

JOHN L. LINDBQUIST, M.D.

MISCELLANEOUS

A Study of Penetrating War Wounds of the Abdomen in the Finnish Fighting Forces During the War of 1941-1944 E. TITTINEN *Ann. chir. fenn.* 1949, 38 Supp. 2

The warfare in this case was carried on in the north of Finland, partly north of the Arctic Circle, for the most part in sparsely settled forest districts, and distances for transport were therefore comparatively long. Weather conditions were poor, with long, cold winters and much snow. There was a lack of buildings, lack of space, poor conditions for the care of the wounded, and a shortage of trained surgeons. In fact, in the words of the author, it can be said that "when a small country like Finland is at war with a great power there is a lack of everything except enemies."

The data upon which this report is based is from the death certificates, the discharge notices and the clinical reports of the surgically treated patients. Only those with injuries of intra-abdominal organs were included in the statistics. In the Finnish Army,

during the war of 1941 to 1944, the patients with penetrating abdominal injuries numbered 3,471—an incidence of 1.6 per cent of the killed and wounded. This figure is lower than that reported from other fronts both in this war and in previous wars.

Of the patients with abdominal wounds, 2,089, or 60.1 per cent, were operated upon. The mortality rate in this group was 66.3 per cent, and if we include patients with abdominal injuries who died without operative intervention, the mortality is 79.7 per cent. Wounds from shell fragments were more common than bullet wounds, the mortality from bullet wounds was higher, probably because of greater velocity of the missile.

The total operative mortality was 66.3 per cent. Wounds of the small bowel had the best prognosis, the mortality in these was 58.6 per cent.

The next most common wounds, in order of their frequency, were small and large bowel wounds, large intestinal wounds, liver wounds, and stomach wounds. The highest mortality occurred in patients with wounds of the spleen. In 968, or 46.3 per cent of patients with abdominal wounds operated upon, there were coexisting injuries. Patients with thoraco-abdominal wounds numbered 146 (7.0 per cent), and the mortality in these was 80 per cent. There were 2 patients with pancreatic injuries and both died. A high mortality occurred among patients with vascular injuries.

In wounds of the colon, simple suture gave the best results, with a mortality of only 61.6 per cent. The mortality following resection of a portion of the colon was 79.3 per cent, and following exteriorization of a portion of the colon, 90.5 per cent. Exteriorization and colostomy were apparently used only in the severest wounds.

The most common cause of death was shock. Patients operated upon between 3 and 10 hours after being wounded had a lower mortality than those who were operated on under 3 and over 10 hours after being wounded. The apparent reason is that in those patients operated upon within 3 hours, shock was not recognized or had not become clinically evident, while in those operated upon after a period of 10 hours, shock was more profound and could not be corrected. Among those patients operated upon between 3 and 10 hours the mortality was lower, probably because shock had been corrected preoperatively, during operation, and postoperatively. With regard to wounds received in 1944, it is also true that when adequate shock treatment had been instituted, particularly the adequate use of blood and plasma, the mortality rate dropped. During the 2 days immediately following operation, 961 patients died (69.4 per cent of all postoperative deaths). Most of these deaths occurred as the result of shock. From the third to the fifth day 170, or 12.3 per cent, of the operative patients died. Most of these deaths were due to peritonitis with paralytic ileus.

Of the 705 patients with perforating abdominal wounds who had undergone operation, only 184 had wounds that healed by primary intention. For this

reason the author believes that despite the administration of sulfonamides (they did not have penicillin), most of these wounds should have been closed secondarily. The majority of those patients who recovered were fit for military duty of some sort. Only 54 were unfit, mainly because of coexisting wounds that produced some permanent disability.

In the light of the statistics presented, the author discusses methods of lowering the mortality. These include effective shock treatment as the most important single item. He believes that shock treatment should be started immediately at the Battalion Aid Station, and carried on before and during operation, too extensive operative procedures should be avoided, the number of qualified surgeons should be increased, colostomy is imperative in rectal injuries and exteriorization should be used more frequently in colonic injuries, if primary suture of the colon is carried out a proximal colostomy should be done. Postoperative observation of the fluid balance and the treatment of paralytic ileus by Miller Abbott tubes is important. FREDERICK C HOEBEL, M D

Massive Penicillin Therapy of Abdominal Actinomycosis GILMAN E SANFORD and RICHARD O BARNES *Surgery*, 1949, 25 711

Two patients with severe abdominal actinomycosis who had failed to respond to therapy with penicillin

in doses of 800,000 units per day plus sulfonamides, adequate surgery, and supportive treatment over periods of 8 and 9 months, respectively, showed dramatic response to massive penicillin therapy. The only change in the treatment of these patients was that of the administration of massive doses of penicillin.

In 1 case penicillin was administered as a continuous intravenous drip for 24 hours a day, in a dosage of 10,000,000 units per 1,000 c.c. of normal saline solution or 5 per cent glucose solution for 7 days, which was then reduced to 1 daily intravenous injection of 10,000,000 units in 1,000 c.c. of saline solution plus 500,000 units given intramuscularly every 3 hours until the twenty-fourth day. Ten days later the daily intravenous injection was discontinued and the intramuscular injections were reduced to 100,000 units every 3 hours. This dosage was continued for 4 weeks. The second patient, who also had a subphrenic abscess, received a similar course of treatment.

One patient was apparently cured in 63 days after an illness of 16 months and the other in 48 days after an illness of 9 months. Both patients were observed for a year after their discharge but there were no signs of recurrence. No toxic effects of massive penicillin therapy were noted.

JOHN L. LINDQUIST, M D

GYNECOLOGY

UTERUS

The Uterine Roentgenogram with Respect to Function, with the Exclusion of Malformations
(Das Röntgenbild des Uterus in Hinblick auf seine Function—unter Ausschluss der Missbildungen) E. PHILIPP *Geburtsh & Frauenh*, 1949, 9 151

The author attempts to draw conclusions with respect to labor and delivery from roentgenographic and hystero-graphic studies. Various deviations from normal are discussed. The author states that the hypoplastic uterus with a triangular uterine cavity is to be differentiated from the "transitional type" which is characterized roentgenographically by a uterine cavity which is triangular, but with pointed angles. The former type of uterus affords a better prognosis with respect to labor and delivery than does the latter.

The author also discusses cervical changes which are visible roentgenographically, in addition to acute pathologic ante-flexion and an enlarged uterine cavity. Since only one each of these conditions was observed, he draws no definite conclusions.

WARREN R. LANG, M D

Clinical Classification of Carcinoma of the Endometrium (La clasificación clinica del carcinoma del endometrio) ANDRÉS RIESCO U *Bol Soc chilena obst gin*, 1948, 13 378

An analysis of 49 cases of carcinoma of the endometrium observed at the National Institute of Radiation during the period from November, 1930 to January, 1944 shows that data pertaining to the size of the uterus found at bimanual examination is recorded in only 25 cases and that the terms used are "normal size," "slight increase," "increased," and "increased in size." In addition, it is impossible to evaluate the late results of treatment since 11 of the 25 patients did not return for follow up examinations. Data on hystero-metry are given in only 15 cases. Data on partial or total infiltration of one or both parametria are available in 17 patients and for one reason or another, none of the patients can be regarded as cured. All of these factors indicate that up until now, no clinical classification has been followed in this country (Chile), and that the statistics do not provide the necessary data to place these patients (retrospectively) in one of the known classifications. Therefore, the author proposes a classification that is precise and can be easily used after a methodical gynecologic examination has been made. It is based on the observations of Healy and Brown and has been adapted and modified for classification by Norman Miller, in addition, the condition of the parametria has been taken into consideration. It is not claimed that this classification is a perfect one,

but it will serve as a starting point in the orientation of this basic aspect of the neoplasm in question.

With this classification the patients are divided into four grades (I to IV) in which, respectively (1) the parametria is free, (2) is free, (3) one or both is partially infiltrated, (4) one or both is totally infiltrated, (1) hystero-metry shows 7 cm or less, (2) from 8 to 11 cm, (3) from 12 to 14 cm, and (4) more than 14 cm, (1) the size of the uterine body is small or normal, (2) corresponding to a pregnancy of from 1½ to 2 months, (3) 2½ to 3 months, and (4) more than 3 months, (1) metastasis or cachexia is absent, (2) metastasis or cachexia is present, (3) vaginal metastasis is present, and (4) distal metastasis or cachexia (or both) is present.

Since hystero-metry and the size of the uterine body may be modified by the coexistence of fibromyoma, the important symptom for this classification will be the condition of the parametria, whether there is a fibromyoma or not, that is, provided there is no distal metastasis or cachexia which would place the patient automatically in grade IV. If there is no parametrial infiltration, hystero-metry will be the decisive sign for the classification. Finally, the size of the uterine body, as found by bimanual examination, and as compared to the size of the pregnant uterus, will determine the grade of the classification, and that hystero-metry cannot be performed always provided there is no parametrial infiltration.

RICHARD KEMEL, M D

ADNEXAL AND PERIUTERINE CONDITIONS

Remarks on the Pathologic Physiology of Endometriosis on the Occasion of 3 Observations of Endometriosis of the Posterior Vaginal Vault (Remarques sur la physiologie pathologique des endométrioses, à propos de trois observations d'endométriose du cul de sac postérieur du vagin) P. MOCQUOT and R. MUSSET *Gyn obst*, Par, 1949, 48 135

Like the uterus itself, an endometriosis reacting to the ovarian hormones undergoes all the changes of the sexual life and of the periodic genital cycle of the woman and is found only in women with sexual activity. It undergoes a decidual transformation during pregnancy. All this shows that typically, in the more evolved and more active forms, the endometriosis is closely subjected to the influence of the sexual hormones. On the other hand, there is no doubt that many endometrioses, after a more or less prolonged period of serious functional disturbances, remain or become completely refractory to sexual hormone stimulation, and that during pregnancy, despite a considerable hormonal overload, the transformation of the endometriosis is not at all inevitable. The authors have studied 3 cases in which the endometriosis (being present in the posterior vaginal fornix) was easily accessible to biopsy.

GYNECOLOGY

of pruritus of the anterior portion of the vulva which had persisted for 6 months. The pruritus developed after each micturition almost like a paroxysmal attack, persisted for a time, and then diminished or even subsided altogether until the next micturition. Recently she had observed slight traces of blood on her linen, and this caused her to seek medical advice.

A general examination and examination of the urine yielded negative results. Examination of the clitoris and of the adjacent portion of the labia minora for $1\frac{1}{2}$ cm revealed a swelling resembling a strawberry, of a reddish brown color, and partly covered with fine whitish pellicles and partly with superficial excoriations. Palpation gave the impression of a chronic edema, a little firmer at the base, but otherwise of a fairly even consistency and not especially hard. Neither the glands nor other genital organs were involved. An epithelioma of the clitoris was suspected, but the lack of induration, deep infiltration, ulceration, and adenopathy after a duration of 6 months seemed to refute such a diagnosis. A wide excision was done including a large part of the labia majora, the clitoris, and all of the labia minora. Histologic examination revealed Bowen's disease. The lesion was considered precancerous, or perhaps an epithelioma in a localized stage. Healing occurred by primary intention and re-examination 3 months later revealed perfect cicatrization. The lesions of Bowen's disease may run an apparently benign course for a long time, even for years, but sooner or later a sudden malignant transformation takes place, either with invasion of the adjacent tissues and lymph glands with rapid metastasis to other organs, or with ulceration and deep penetration but no invasion of the lymph glands, and thus it remains localized.

When cancer supervenes, it is usually of the spinocellular type, but some forms more like the basocellular cancer have been described. Mucosal involvement usually differs from the cutaneous lesions and the course, although slow, is more rapid than that of the cutaneous lesions, and is very often accompanied by attacks of pruritus following irritation of any kind. Bowen's disease of the mucosa and erythroplasia are synonymous. Diagnosis is made by biopsy and microscopic examination, and differentiate it from tertiary syphilis, psoriasis, psoriasiform affections, lupus erythematosus, and senile keratosis. Opinions differ as to the frequency of malignant degeneration, which is usually common in the mucosal type of the disease. Histologically, some regard the lesion as precancerous, others as cancerous from the start. Treatment consists in excision, electrocoagulation, or roentgen or radium therapy.

MISCELLANEOUS

Culdoscopy ALBERT DECKER *J Am M Ass*, 1949, 140: 378

With the patient in the knee-chest position, the rectovaginal pouch may be punctured with a needle

or trochar by a technique that is simple and safe. Endoscopic visualization of the female pelvis was attempted in 77 cases in which the diagnosis made by other means was indefinite or doubtful. The examination was successful and of diagnostic value in 88.3 per cent of the cases selected. The puncture was unsuccessful in 9, or 11.7 per cent, of the cases. When the puncture was possible, detailed information was obtained concerning the disease present. The procedure was particularly useful in disclos-

ing 2 cases of tuberculosis, 4 cases of endometriosis, and 1 case each of adenomyosis and ovarian neoplasm.

The culdoscopic diagnosis was verified at operation or by subsequent events in all cases. On occasions exploratory laparotomy in suspected surgical emergencies was avoided. A more prompt diagnosis has in some instances resulted in the reduction of days of hospitalization and in the number of clinic visits. The procedure has been useful in the solution of problems of menstrual abnormality. In 13 selected infertility problems, detailed information was gained concerning the condition of the tubes and ovaries.

There were no serious complications or accidents in these cases. Culdoscopic visualization is a useful and harmless diagnostic procedure that allows a prompt and positive diagnosis in a large variety of gynecologic problems not readily diagnosed by the usual methods.

CHARLES BARON, M D

The Effects of Various Estrogenic Preparations Changes in the Vaginal Mucosa and General Status of Climacteric Women Following the Injection of Aqueous Suspensions of Estrone and Estradiol MILDRED VOGEL, THOMAS H MCGAVACK, and JOSEPH MELLOW *Am J Obst*, 1949, 57: 682

The standardization of estrogenic material for use in human beings and the necessary dosage to yield clinical therapeutic results are problems of no mean proportion.

The preparations used in this study were aqueous suspensions containing 2 mgm of estrone and 0.5 mgm of estradiol administered in 1 cc and 2 cc doses, respectively. Twenty-three women with climacteric symptoms were the subjects of this study. Following a control period, injections were given at 3 week intervals. Vaginal smears were utilized to obtain objective evidence, and this was correlated with the patient's subjective response.

The injection of estrone was followed by some degree of follicular stimulation of the vaginal epithelium in 69 per cent of the test subjects. The average "lag-time" following the injection of 2 mgm estrone was 120 hours, 4 mgm of estrone, 101 hours, 0.5 mgm of estradiol, 99 hours, and 1 mgm of estradiol, 91 hours. Estrogenic effects on the vaginal mucosa due to the injection of 2 mgm of estrone lasted 120 hours, 4 mgm of estrone, 110 hours, 1 mgm of estradiol, 99 hours, and 1 mgm of estradiol, 91 hours.

The height of the estrogenic response in the vaginal mucous membrane varied widely and could not be correlated with the amount of hormone administered

Symptomatic relief from climacteric symptoms was experienced by 21 of the 23 women. A cumulative action could be demonstrated as a result of repeated injections. The relief of subjective symptoms could not be correlated with the objective response as shown by the vaginal smear examination

JOHN R. WOLFF, M.D.

The Genitocolitic Syndrome (Sindrome genito colitica) CARLO VERCESI *Ann ostet gin*, 1949, 71 3

On becoming director of the Obstetric and Gynecologic Clinic of the University of Milan, Italy, the author spoke on the rehabilitation of women with so-called colitis, which he maintains has its origin in gynecologic disorders. The chief primary cause of this syndrome is genital tuberculosis in the young female. Later, tuberculosis heals, or at least becomes quiescent. In the colitic cases the left side is usually the part involved.

The patient is generally slender in build, poorly nourished, and more or less anemic. The symptoms are usually periods of constipation alternating with those of diarrhea, abdominal distention, dyspeptic symptoms, and pains, the pains are reflected toward the anus (dyschesia) and upward along the sigmoid and descending colon, to reach on occasion as far as the epigastrium. On examination the uterus is found to be poorly developed, more or less retroverted, and pulled to the left. There are indurative changes in the left broad ligament, especially near the upper peritoneal surface. Perhaps a hydrosalpinx is present. The entire side of the pelvis is more or less fixed and painful to palpation.

The medical man, despite the history of dysmenorrhea, relative sterility, and evident aggravation of symptoms after marriage and during the menstrual periods, frequently continues to treat the

condition as a simple colitis (diet, spa-treatment, vitamins) without thinking to refer the patient to a gynecologist for examination, and for the possible benefits of therapy directed at the gynecologic condition.

The therapy employed by the author in milder cases has frequently been limited to the simpler medical gynecologic procedures (medicated douches, hot applications to the lower abdomen, opotherapy aimed at promoting a proper uterine development). In the more severe conditions operation has at times been necessary. The uterus is brought back to its normal midline position by a right-sided antero-fixation (Alfieri method), the worst adhesions and indurative processes perhaps excised, and corrective surgery, when indicated, performed on the tube. Of course, the left adnexa may have to be partially or completely removed.

The author's experience with these therapeutic measures has now extended to 35 cases. Eighteen of the patients exhibited a mild condition and were treated medically. All of them received decisive and permanent benefit. Some of the patients were married and, although denied the privilege of motherhood, the married state did not produce a recurrence or even an aggravation of the condition. Eleven women presented advanced conditions of both the gynecologic and colonic regions but refused operation, or operation was contraindicated for some reason. These patients did not receive any considerable benefits from either the usual medical colitic or gynecologic methods of treatment. Six of them were subjected to operation and all received pronounced benefit from the procedure. Two of those treated by centralization of the uterus and by excision of the left tube and ovary later became pregnant. In one of these an abortion occurred, in the other there was successful delivery of a living male child at full term. This child is now in school and is in very good health.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

The Diagnosis of Tubal Pregnancy (Zur Diagnose der Tubargravidit t) A W SCHWENZER *Geburtsh und Frauenh*, 1949, 9 336

The author discusses the difficulties in the diagnosis of extrauterine pregnancy. Twelve cases are described in detail in which the diagnosis had either been missed altogether, or could be ascertained only after a longer period of clinical observation.

The value and limitations of the Aschheim-Zondek reaction and of aspiration of the cul de sac are discussed.

WERNER M SOLMITZ, M D

Diabetes Insipidus and Pregnancy (Diabete insipide gravidanza) PIERO STRADELLA *Ann ostet g n*, 1939 71 90

Two examples of the rare complication of diabetes insipidus in the pregnant state are added by the author to the 57 already reported. Of the 57 patients with typical symptoms of polyuria and polydypsia during the pregnant period, only 22 developed the condition during the pregnancy itself. It is consequently only in these 22 cases that it might be hypothesized that the pregnant state was the cause of the polyuria. In all of these pregnant women the polyuria and polydypsia disappeared during the puerperium.

That the author's 2 cases were instances of true diabetes insipidus—although the polyuria was never excessive—was indicated by the constant alkalinity of the urine, and the results of the Veit test for salt tolerance. This test was given in one patient by the typical Veit technique, consisting of the oral administration of 20 gm of salt in 500 c.c of water, in the other patient the test was the same with the exception that only 10 gm of salt were given. Both of the patients reacted typically for primary polyuria, or true diabetes insipidus, by an aggravation of the polyuria and increase in the chlorides of the urine, but with no change in the normochloremia of the first patient, nor in the hypochloremia of the second. Therefore, in true diabetes insipidus the salt is thrown off in the urine and postulates for this condition a lack of capacity of the kidney to retain the salt, while in the hypothesized secondary, or symptomatic, form of polyuria the reaction to the test consists of an increase in the chlorides of the blood and a decrease in the polyuria and polydypsia.

That these 2 cases belong in the category of the 22 cases cited in the introductory paragraph is indicated by the fact that in the one the polyuria apparently appeared in the second month of pregnancy and disappeared in the eighth month on the implantation of the posterior hypophyseal lobes of 2 calves, and that in the other the disturbance developed in the sixth month of pregnancy and disappeared

spontaneously during the puerperium. In both of these patients the pregnancy ran an otherwise normal course and delivery resulted in perfectly normal children.

The benefits derived by the patient who received the implantation of posterior hypophyseal tissue lends support to the theory with reference to the antidiuretic effect of the posterior lobe of the hypophysis and its depression or failure in diabetes insipidus. Whether this effect is obtained by a counteraction against some diuretic principle of the anterior lobe, either as the direct effect of its own secretion, or indirectly through the action of this lobe of the hypophyseal gland on other glands of the endocrine system (thyroid, adrenal glands) remains an open problem.

JOHN W BRENNAN, M D

PUERPERIUM AND ITS COMPLICATIONS

Artificial Delivery and Morbidity of the Puerperium (D hvrance artificielle et morbidit  des suites de couches) R KELLER and L GIOANNI *Gyn obst*, Par, 1949, 48 168.

In a previous communication on the indications of uterine revision, the authors have shown that this intervention is not dangerous and is not a factor aggravating the puerperium. Now they feel justified in stating that, contrary to the generally accepted opinion, artificial delivery is not a dangerous intervention either.

Their study included 7,000 deliveries. In 148 of the patients, artificial deliveries were performed, an incidence of 2.11 per cent, which is higher than that of most other authors. The difference is due to divergences in the indications, which may be grouped under two main headings: (1) hemorrhage, whether the placenta is partially detached or the detached placenta is not expelled by an atonic uterus that is bleeding, (2) retention of placenta, whether the placenta remains attached (abnormal adherence, placenta accreta) or is more or less detached but is incarcerated. In case the placenta does not become detached, the authors do not wait more than 2 hours before intervening. Before performing artificial delivery they try manual expression—if necessary, under general anesthesia.

Artificial delivery is performed as carefully as possible, and with the greatest asepsis of the genital passages, and of the hand used, an intravenous injection of posterior lobe extract is given systematically. In the 148 cases there was no mortality. The total morbidity was low, quantitatively (11.7 per cent) and qualitatively, and was only partly due to the intervention. Other factors which aggravate the morbidity of the puerperium are severe hemorrhages, general diseases coexisting with pregnancy, disorders natural to pregnancy, obstetrical interventions, and the febrile conditions present at the time of delivery.

whether their cause is obstetrical or not. The role of the duration of labor deserves special mention, the chances for morbid sequelae increase with the prolongation of labor. In addition, the prognosis of artificial delivery, like that of uterine revision, becomes worse with delay, finally, certain local conditions, such as placenta accreta and abnormal adherence, increase the morbidity of the intervention.

From the practical point of view, it is useful to remember that a number of factors may increase the morbidity of the puerperium. Some of these, such as abnormal local conditions, general and obstetrical disease, fever at the time of delivery, etc., are unavoidable. In other cases an attempt should be made to decrease the risks of artificial delivery by using an anti-infectious prophylaxis. The authors have not used a systematic prophylaxis, but have administered sulfonamides or penicillin in febrile cases, in difficult or hemorrhagic labors, in those having occurred elsewhere, and in cases of laborious detachment of the placenta. In general, the results obtained were satisfactory. But there are other factors whose interference may be avoided or decreased. The first is the introduction of exogenous infection, the second is a too long delay between birth and artificial delivery which increases blood loss and the risk of infection. Finally, an attempt must be made to shorten the duration and improve the quality of labor by using the method of Kreis, which seems to be the best (spasmalgia, rupture of the membranes on small dilatation). The last improvement consists of the systematic intravenous injection of posterior lobe extract after artificial delivery.

RICHARD KEMEL, M D

Delayed Hemorrhage Following Delivery Hemorrhagic Type of Puerperal Infection of Couvelaire (Hémorragie tardive des suites de couches. Forme hémorragique de l'infection puerpérale de Couvelaire) JEAN SNOECK and M. ROCMANS. *Gyn obst*, Par, 1940, 48: 11.

A severe case of the hemorrhagic type of puerperal infection is reported. The comparative rarity of this formidable complication of delivery warrants the publication of this report.

The patient, a woman 30 years of age, was a quadripara. In the years of 1934 and 1936 she had been delivered by cesarean section, both of which operations were complicated by endometritis and infection of the abdominal wall. In 1937 she had had a spontaneous delivery of twins during the seventh month of pregnancy.

On November 29, 1938 she developed labor pains in her fourth pregnancy. An hour after labor began, an increasing hypertonicity of the uterus necessitated the administration of three doses, of 1 cc each, of spasmalgia. About 7 hours after labor had begun, the cervix was dilated the size of the palm of the hand.

The fetal membranes were ruptured artificially. The amniotic fluid was the color of purée of peas. The fetal heart sounds were barely audible.

Eight hours after labor had begun, surgical intervention was decided upon and cesarean section with sterilization was performed. On opening the abdomen, the uterus was found adherent to the peritoneum throughout its entire length. The bladder appeared immediately in the bottom of the wound. At the bladder level and in the area of the lower uterine segment, there was a large mass, which on being incised was found to be a collection of thick greenish amniotic fluid. There was a rupture of the uterus in the middle of the horizontal scar of a previous operation. After delivery of a live baby, sterilization was carried out.

The same night in which surgical intervention was carried out, the patient developed fever, and a blood culture which was taken was positive for the pseudodiphtheria bacillus. The patient's wound healed by primary union. There was an abundant normal lochia.

Nine days postoperatively the patient expelled three large clots and, later, showed the classical signs of massive hemorrhage, which necessitated blood transfusions. Vaginal examination revealed the cervix dilated to two fingers, and the vagina and the uterine cavity were filled with large clots. The patient's temperature was elevated for 2 days.

Seventeen days after delivery, a new hemorrhage with an abundance of bright red blood occurred and the patient collapsed. Three blood transfusions were given.

On the twenty second day after delivery, a third massive hemorrhage occurred. A hysterectomy to control the hemorrhage was decided upon. At operation, the uterus was found to be the size of a grapefruit. The walls of the uterus were hard and pallid. The myometrial vessels were dilated. The uterine cavity was gaping and empty and gave off a fetid odor.

The uterine mucosa was thickened. In the lower part of the uterus were numerous petechial thromboses and small ulcerations.

Microscopically, at the site of the placental insertion, there were areas of regeneration and numerous superficial areas of necrosis. Throughout the entire submucosa there was extensive leucocytic infiltration. Numerous vessels were thrombosed. No chorionic elements were present and there were no microorganisms visible.

Bacteriological examination showed colon bacilli, staphylococci, streptococci, and anaerobic bacteria.

This case represents two interesting clinical points.

The first was the insidious rupture of the uterus at the beginning of labor. This rupture occurred in the lower segment of the uterus at the site of an old scar of a former operation. The lesion, veiled by extensive adhesions, was practically without symptoms and had done no harm to the fetus.

The second point, the more important of the two and the one which dominated the clinical picture, was the septic hemorrhagic symptom of Couvelaire.

The puerperal infection occurred first. Its presence was demonstrated by the febrile attack and

the positive blood culture made directly after labor. After an 8 day afebrile period, the first massive hemorrhage occurred and other hemorrhages occurred at more frequent intervals. The hemorrhages were accompanied, or followed, by fever. This particular picture is classical for the hemorrhagic type of puerperal infection.

The causative organisms shown by blood culture and anatomopathologic examination of the uterine lesions confirmed the diagnosis.

Clinically this case was more hemorrhagic than septic. In spite of the blood transfusions hemorrhage was massive and recurred so often as to endanger life. The intensity of the cardiovascular collapse with each hemorrhage was impressive.

Temporary medical treatment was tried and after its failure, radical operation was necessary.

The pathogenesis of this case warrants discussion. First each hemorrhage was followed by a period of calm. It appears that the thrombosis of the vessels produces purulent foci accompanied by necroses of the uterine submucosa and mucosa.

A fresh massive hemorrhage occurred only when the lytic phenomena produced a vascular phase stronger than the thrombotic phase.

The hemorrhage, being so massive and difficult to control by ordinary means (ice, ergometrine) proved that the vessels were widely dilated and that the tissues which they supplied were so infiltrated by leucocytes as to produce a severe infection and a complete loss or great diminution of the ability of the vessel to contract.

This pathogenic mechanism calls to mind certain infectious and hemorrhagic phenomena observed at times at the site of amputations.

It is fair to say that the vascular thromboses in the hemorrhagic zone were necessarily infected and that if in general they did not appear to go beyond the depth of the myometrium, they were primarily infected thromboses and eventually developed into abscesses. This explains satisfactorily the febrile episode which preceded or accompanied these hemorrhages. These febrile episodes were the result of bacteria or toxins being thrown into the patient's blood stream. The predominance of vascular or septic phenomena will determine whether the syndrome of Couvelaire will be chiefly hemorrhagic or chiefly septic. In the one as in the other, the primary lesion is a uterine wound, without placental retention, in the process of septic necrosis with extensive infection of the mucosa, submucosa, and myometrium. In the authors' opinion the infected thromboses which are consistently observed are the primordial lesions. BLACKWELL MARKHAM, M.D.

Puerperal Scarlatina (Puerperalscharlach) WILLI SCHULTZ. *Geburth & Frauenh.*, 1949, 9: 251.

The author discusses an epidemic of scarlet fever and other streptococcal infections which occurred in a small maternity hospital in Hamburg, Germany, in 1936, that is, before the era of antibiotic treatment and chemotherapy.

Thirteen women were affected. Puerperal scarlatina developed in 8 patients, puerperal erysipelas of the vulva in 1 patient, necrotizing mastitis with erysipelas in the area of the breast developed 5 weeks after delivery in 1 patient, 3 other cases concerned 2 nurses and a midwife, one of whom had a typical case of scarlet fever, and the other 2, tonsillitis caused by hemolytic streptococcus. Two of the 8 patients with puerperal scarlatina died.

As to the clinical course, the puerperal scarlatina started between the second and the seventh day after delivery. The exanthema began in the area of the vulva and perineum and spread to the abdomen and thighs. The Schultz-Charlton test was positive. As is known of surgical and puerperal scarlatina in general, there was no tonsillitis or other throat involvement present in the patient in whom the birth canal was the portal of entry.

To stop the epidemic, the hospital was closed and thoroughly disinfected three times. However, after each reopening new cases occurred. Only after the fourth wave of diseases of this type was it found that the midwife was a carrier of virulent hemolytic streptococci. She was dismissed from the hospital, and no new cases occurred after her leaving. The author states that "for external reasons" he was not able to publish a report of this interesting epidemic earlier than 13 years after its occurrence.

MISCELLANEOUS

Physiopathology of the Uterine Contraction (Fisiopatología de la contracción uterina). JOSÉ RAMÍREZ OLIVELLA. *Rev. cubana obst.*, 1948, 10: 103.

Disturbances of uterine tonus (hypotonus and hypertonus) may affect the useful force of the contractions of labor. The functional disturbances of the contractions may be due to insufficient, or to excessive contraction. Disturbances due to insufficient contraction result in inertia which may be primary or secondary. Primary inertia may be caused by pathologic changes in the uterus (fibrosis, sclerosis, overload of fat, etc.) or to a defect in the stimulation of the muscle fiber which may be anatomically normal. Treatment consists of fractionated doses of pitocin (2.5 units every 15 minutes), calcium gluconate intramuscularly, sparteine sulfate (15 to 20 centigrams), or of any other gentle stimulant of uterine contraction. Secondary inertia is the result of muscular fatigue caused by struggling against an obstacle, its treatment consists of spasmolytics to obtain uterine rest for a period of 1 or 2 hours, followed by stimulation by oxytocics.

The functional disturbances due to excess of contraction are more numerous. Polysystole occurs as the first phase of the struggle against an obstacle, and causes fetal suffering. It is treated with spasmolytics. Subinert contractions, which result from an increase in the frequency of the former with decrease of the interphasic period, require the same treatment. Uterine tetanus is a more advanced phase

of the preceding conditions, leads to contracture or secondary inertia, causes severe fetal suffering and requires deep general anesthesia and treatment with spasmolytics. Uterine contracture constitutes the highest degree of contraction dystocia in which pains and fetal heart beats disappear, labor stops, the patient becomes exhausted, and the impossibility of spontaneous birth makes surgical intervention imperative. Exceptionally the low, but always risky, route may be used. Only with use of the high route, with the uterus in view, is it possible to decide whether cesarean section or hysterectomy is indicated.

The functional disturbances of uterine contraction with functional asynergy include the syndromes of Schickelé, Demelin, and Bandl. If discovered in time, the syndrome of Schickelé may be easily overcome by the administration of spasmalgin, which contains papaverine, pantopon, and sulfuric ether of atropine, the dose is one ampule every 20 minutes up to three doses, and the series may be repeated two or three times. When the syndrome is not discovered in time and the cervix is truly edematous, radiating incisions of the cervix are necessary. Early diagnosis of the syndrome of Demelin is necessary since its initial phases are easily overcome by spasmolytics, once there are anatomic changes, treatment must be surgical. In the syndrome of Bandl, treatment depends upon the type of fetopelvic disproportion and the condition in the individual case, it may consist of symphysiotomy, abdominal cesarean section, or fetotomy.

Many of the dystocias of uterine contraction can be avoided by prophylactic treatment. In a revolutionary concept of the prophylaxis of spasmodic pictures, especially of the uterine cervix, the Strasbourg School, with Schickelé at its head, considers that the persistent presence of the amniotic sac is a frequent cause of spasmodic disturbances of uterine contraction, and has initiated two new methods: the medical parturition of Kreis, based on early rupture of membranes and the use of spasmalgin in the presence of good fetopelvic proportions, and the directed parturition of Voron and Pigeaud which differs from the former only in the addition of the use of oxytocics, such as hypophysis extracts in 2 unit fractionated doses, or quinine sulfate in fractionated doses of 0.50 gm. to reach the total dose of 1.5 gm., and of antispasmodics, including spasmalgin and chloral hydrate.

RICHARD KEMEL, M.D.

Is the Hegar-Sellheim Internal Pelvic Examination Unnecessary? (Ist die innere Beckenuntersuchung nach Hegar-Sellheim ueberfluessig?) A. MAYER. *Geburthl. & Frauenh.*, 1949, 9, 307.

Several outstanding obstetricians in Germany lately declared that pelvimetry is obsolete, and they rely entirely on the test of labor in determining whether cesarean section is indicated. The author criticizes this new trend severely and emphasizes the importance of correct internal pelvic measurement. A "functional diagnosis" is justified only in borderline cases. The aim of modern obstetrics

should be to diagnose a narrow pelvis during pregnancy.

A disadvantage of the "functional diagnosis" is that it gives information only about the inlet. If the inlet is normal but the outlet narrow, the time for section has been missed and the life of the baby may be in jeopardy. On the other hand, neglect of pelvic measurement and reliance on the functional diagnosis often lead to unnecessary cesarean section. The author refers to several instructive cases in which section was done for an alleged narrow pelvis although the internal measurements were perfectly normal.

External pelvimetry is of little value. Gracile innominate bones and the vertical position of the iliac alae may give quite low external measurements although the pelvic lumen is entirely normal.

WERNER M. SOLMITZ, M.D.

The Action of Folliculin and Progesterone on the Water Metabolism in Pregnancy (L'azione della follicolina e del progesterone sul metabolismo idrico in gravidanza). TIMOTEO NOBILE. *Ginecologia*, Tor., 1949, 15, 53.

In this study the author has used four groups of 6 pregnant guinea pigs each, all of which were at least in the second half of their pregnancy. The first group served as controls. All animals in the other three groups were given an intraperitoneal injection of 10 c.c. of Ringer's solution daily for 3 days, but the third group received in addition 5 mgm. of progesterone daily for 3 days, and the fourth group received 20,000 units of folliculin daily for 3 days. The animals were killed by bleeding after 12 hours of fasting and 24 hours after the last treatment. This was immediately followed by determination of the hematocrit values (with the use of centrifugation for 1 hour), of the protein values of the plasma, (with use of the refractometric method), and of the dry residue of the maternal and fetal organs, by means of double weighing on pieces of tissue that had been left for 90 minutes in the incubator at 110 degrees.

The study showed that in all treated animals there was greater imbibition of the fetal tissues than of the maternal tissues. This is in perfect agreement with the needs of the organism in the process of formation. An interesting fact is that while there are organs, like the liver and the brain, which show only minimal changes in their water content, there are others, like the skin, muscles, blood, and kidneys, which undergo important changes in their water content under the stimulation of the hormones. A peculiarity is that some organs, like the skin and the blood, undergo changes in which a maternal loss of water is compensated by a proportional imbibition of the same fetal tissues. The same cannot be stated about muscles and kidneys which, in the mother, maintain nearly constant values after any treatment, while in the fetus they undergo decided imbibition under the three treatments. However, the peculiar behavior of the uterine tissue should be

noted, it is influenced by Ringer's solution and to a higher degree by folliculin, but only temporarily, or not at all, by progesterone. This shows that the more highly differentiated tissues, whether maternal or fetal, do not undergo important changes in their water content because the function of these cells should not be disturbed. The true water reservoirs of the organism are the skin and the blood, therefore skin and blood changes occur easily in the mother as well as in the fetus.

Progesterone and folliculin act in general to facilitate imbibition of the fetal tissues without simultaneously causing a general water loss in the maternal tissues, this loss occurs only in the maternal blood. In cases in which water loss in the maternal tissues is not accompanied by fetal imbibition, the water must have been eliminated by the excretories.

While the injection of Ringer's solution does not cause changes in the water values of the blood, there is nevertheless a reduction in the corpuscular mass, expressed by the hematocrit data. This reduction can be interpreted as a loss of water from the protoplasm of the red cells. In subjects treated with progesterone there is an increase in the dry residue of the blood, i.e., a dehydration in the absolute sense. On the other hand, folliculin acts to reduce the aqueous mass of the entire blood while the corpuscular mass increases in volume.

The plasma proteins increase after treatment with Ringer's solution but remain unchanged under subsequent hormonal action. RICHARD KEMEL, M D

The Action of Extracts of the Anterior and Posterior Hypophysis on the Water Metabolism in Pregnancy (L'azione degli estratti di ipofisi anteriore e di ipofisi posteriore sul metabolismo idrico in gravidanza) TIMOTEO NOBILE *Ginecologia*, Tor, 1949, 15 71

In the present study the author again used four groups of pregnant guinea pigs (6 animals in each group), all of which were at least in the second half of their pregnancy. The animals in the first group served as controls. All animals in the other three groups were given an intraperitoneal injection of 10 c.c. of Ringer's solution daily for 3 days, but those in the third group received, in addition, 100 international units of anterior lobe extract daily for 3 days, and those in the fourth group received 3 units of pituitrin daily for 3 days. The animals were killed by bleeding after 12 hours of fasting and 24 hours after the last treatment. This was immediately followed by determination of the hematocrit values, using centrifugation for 1 hour, of the protein values of the plasma, using the refractometric method, and of the dry residue of the maternal organs and, when possible, of the fetal organs, using double weighing on pieces of tissue that had been left in the incubator at 110 degrees, for a period of 90 minutes.

The study showed that in all treated animals the fetal tissues presented a higher degree of imbibition than the maternal tissues. The injection of Ringer's

solution caused imbibition of the tissues performing the function of water reservoir (skin and muscle) and left unchanged the water content of the tissues with special functions (liver), or of highly differentiated tissues (brain). The action of extracts of both the anterior and posterior lobes of the hypophysis has a repercussive effect even on the tissues that are most refractory to imbibition, and causes an increase in the water content of these tissues. The action of the two extracts on the water metabolism of the blood, in experiments, does not correspond to that observed in the clinic. In experiments, there is no such antagonism between the anterior lobe extract and the posterior lobe extract as that which seems to be present in the clinic. The hematocrit values (expression of the corpuscular mass) decrease under therapy with anterior lobe extracts, but there is no simultaneous change in the water values of the entire blood. The hematocrit values in patients treated with posterior lobe extracts decrease simultaneously with a decrease in the water values of the entire blood. The plasma proteins increase quantitatively under the action of injection of Ringer's solution and, finally, under the action of both anterior and posterior lobe extracts.

RICHARD KEMEL M D

Contribution to the Study of Reports of Pulmonary Tuberculosis and Pregnancy (Contributo allo studio dei rapporti tra tubercolosi polmonare e gravidanza) E. ROBECCHI and A. BERNABO S-LORATA *Ginecologia*, Tor, 1948, 14 277

One hundred cases of pulmonary tuberculosis complicated by pregnancy are reported by the authors. In the report, these 100 cases are classified as to the outcome of the pregnancy. Five patients had premature deliveries, 69 were delivered at term, 6 patients aborted spontaneously, and 20 were aborted therapeutically.

Ten of the 69 women who were allowed to go to term died within 1 year after delivery, (14.5 per cent of the cases). In 10 other women (14.5%) the pre-existing lesions grew worse or new foci appeared. In 5 of the 69 cases the babies died of tuberculous meningitis.

Of the 20 patients who had therapeutic abortions, 5 (25%) died.

Of the 11 patients who had premature delivery and spontaneous abortion combined, 1 (9.09%) died and 1 became more ill.

A greater number of patients died or grew worse among those with tuberculous cavities, with ineffective pneumothorax, or with the usual forms of active tuberculosis, especially if pregnancy was allowed to go on to term. In the cases with hemogenous apical and extra-apical tuberculosis, with ineffective pneumothorax, and with arrested forms of the disease, the greater percentage of both the mothers and children survived if pregnancy was allowed to go on to term.

Thirty-nine of the authors' cases had had pneumothorax, unilateral or bilateral. In 22 of these

cases, the pneumothorax was termed effective. In 4 of these 22 cases (including 2 of premature delivery) the condition grew worse after delivery and 1 baby died. In 16 cases the pneumothorax was termed ineffective. Among these cases there were 7 of therapeutic abortion and 3 of premature delivery. Of 6 patients in this group allowed to go to term, 5 died within 1 year after delivery and in 1 the condition grew worse. Of the 7 patients therapeutically aborted, 2 died. Of the 3 with premature delivery, 1 died. From these figures the authors conclude:

1. In cases of effective pneumothorax, the greater number of patients go to term with the condition growing worse in a small percentage.

2. In cases of ineffective pneumothorax which are allowed to go to term, the mortality percentage is high.

3. In cases of ineffective pneumothorax with treatment by therapeutic abortion, the percentage of mortality is small.

The advisability of performing pneumothorax during pregnancy should be decided by the collaborating physiologist and obstetrician. The authors are of the opinion that the gravid tuberculous patient treated by effective unilateral or bilateral pneumothorax, if the cardiovascular, renal, and general condition permit, can easily go to term if the collapse has been performed before or during pregnancy.

In case of ineffective pneumothorax or active contralateral lesions, each case must be considered individually as to the possibility that collapse may favorably modify the course of the disease. A bilateral therapeutic pneumothorax should be done if the lesions are comparatively new or there are definite exacerbations of a pre-existing lesion on the opposite side.

In 19 cases of inactive and arrested pulmonary lesions allowed to go to term, the condition grew worse after pregnancy in 3 and 1 patient died from rapid, diffuse tuberculosis. The authors agree with the

consensus of opinion when they advise that pregnancy should not be interrupted in these cases. The danger of activating old foci or giving rise to new foci is too great.

Of the 69 babies born at term, 5 died within a few months after birth. The authors are of the opinion that babies born of tuberculous mothers should be submitted to prophylactic treatment and kept for a time in special institutions for such treatment.

CONCLUSIONS

Therapeutic abortion should be done in cases of pulmonary tuberculosis when pneumothorax has been ineffective.

In cases of nodular apical and extra-apical tuberculosis, pregnancy usually goes to term without harm to the patient and abortion should not be performed in these cases.

Effective unilateral and, rarely, bilateral pneumothorax allow pregnancy to go to term with a very small mortality rate.

In cases of ineffective pneumothorax in premature deliveries the mortality is high. In cases of ineffective pneumothorax treated by therapeutic abortion the mortality is low.

In cases of effective pneumothorax, unilateral or bilateral (cardiovascular, renal, and general condition permitting), pregnancy proceeds favorably to term if collapse has been done before or during pregnancy.

All forms of active tuberculosis predispose the patient to a fatal outcome within a few months after delivery.

Cases of inactive and arrested pulmonary lesions complicated by pregnancy are in danger of reactivation of old foci and the production of new foci.

Babies born of tuberculous mothers should be followed up for 1 year and then checked periodically thereafter by roentgenography. They should be treated prophylactically in antituberculous dispensaries.

BLACKWELL MARKHAM, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Hyperfunctioning Tumors of the Adrenal Cortex, with a Report of 8 Cases WALTMAN WALTERS and RANDALL G SPRAGUE *Ann Surg*, 1949, 129 677

In recent years the combined efforts of internists, pediatricians, chemists (particularly the steroid chemists), physiologists, and surgeons have resulted in substantial additions to knowledge of the syndromes associated with hyperfunctioning lesions of the adrenal cortex. Methods for the assay of urinary steroids have been developed which are helpful in diagnosis and in determining the results of treatment. For patients presenting clinical syndromes known to be associated with hyperfunction of the adrenal cortex, the problem of differentiating between tumor and hyperplasia has been simplified, though not entirely solved, by methods of urinary assay. Thanks to the greater availability of some of the adrenal steroids in natural and synthetic forms, the physiologic effects of several of the hormones in this group have been elucidated by both animal and clinical studies. As a by-product of these studies, it is now possible to explain many (though not all) of the symptoms and signs presented by patients with hyperfunctioning lesions of the adrenal cortices. Metabolic studies and identification of the urinary excretory products of the adrenal steroids have further clarified the pathologic physiology of these lesions.

The clinical pictures associated with hyperfunction of the adrenal cortex are extremely protean in nature and presumably depend upon the type and the quantity of steroid hormones produced, the age and sex of the patient, and perhaps on other factors.

For patients presenting clinical syndromes known to be associated with hyperfunction of the adrenal cortex the problem of differentiating between tumor and hyperplasia has been simplified, though not entirely solved, by methods of urinary assay.

The purpose of the complete article is to present a group of 8 cases of proved tumors of the adrenal cortex which exemplify some of the problems encountered in diagnosis and surgical treatment. These cases supplement the 10 cases reported in 1934 and the 7 cases reported in 1938.

At the time of these earlier reports, methods for assay of urinary steroids were either unknown or were in an early stage of development, and little was known of the effects of pure adrenal steroids.

Desoxycorticosterone has its effect upon salt-and-water metabolism, compounds A, B, E, and F, of Kendall, have an effect on carbohydrate and protein metabolism, and the first two, on fat metabolism. Androstenedione and adrenosterone, estrone and progesterone have androgenic, estrogenic, and progestational effects, respectively.

Edema, hypertension, and congestive heart failure may result from retention of salt and water, and loss of potassium may lead to profound muscular weakness.

Overproduction of hormones having physiologic effects, like compound E and compound F, may explain the diabetes mellitus, the negative nitrogen balance, the muscular weakness, the osteoporosis, the thinning of skin, and the ecchymosis, and the effect of lymphoid tissue may explain the leucopenia which is characteristic of Cushing's syndrome.

Virilism, hirsutism, baldness, amenorrhea, florid skin, hypertrophy of the clitoris, acne, masculinization of the voice in women, and alteration of the habitus in the direction of masculinity might result from the production of an excessive amount of androgenic material by an adrenocortical tumor—and likewise the occurrence of sexual and somatic precocity in children.

Overproduction of estrogens and of compounds having an action like that of progesterone may explain the vaginal bleeding and sexual precocity in girls who have tumors of the adrenal cortex and the occurrence of impotence and gynecomastia in men.

Lastly, and of extreme importance, is the fact that a patient with a hyperfunctioning tumor of the adrenal cortex and virilism is likely to excrete a large amount of 17-ketosteroids in the urine, and, on the contrary, if evidence of virilism is minimal or lacking, as in Cushing's syndrome, the excretion of 17-ketosteroids may not be elevated.

Addisonian Crisis JOSEPH J KRISTAN *J Urol*, Balt., 1949, 61: 178

The author reports a case of latent adrenal cortical insufficiency in which the diagnosis was made and treatment instituted only after nephrectomy had been done for renal tuberculosis. The possibility of concurrent complicating diseases masking the diagnosis of cortical insufficiency should be considered in all patients with urogenital tuberculosis, especially those in whom surgery is contemplated.

The patient whose case was studied was a 37 year old white male who gave a history of weakness, dizziness on changing position, and headache with nausea, suffered over a period of 7 years. Thyrotoxin therapy, only partially alleviated his symptoms. On several occasions he had noted pink seminal fluid. Slight frequency was the only urinary symptom. Investigation revealed left renal tuberculosis. Following a left nephrectomy, the blood pressure remained low in spite of multiple transfusions. Adrenal insufficiency was suspected. Cortical extract (cortate), 10 mgm at once and 5 mgm every 6 hours, was given. The blood pressure response was good but the patient appeared very ill, vomiting moderately. The immediate postoperative course was somewhat stormy but after 2 weeks the patient was discharged without further

cortical extract therapy The pathological diagnosis was ascending tuberculous pyelonephritis

Three days after discharge the patient became progressively worse and returned to the hospital in collapse The systolic blood pressure was 60 and 70 mm Hg Ten milligrams of cortate and salt, in amounts up to 9 gm, were given daily The blood pressure ranged between 70 and 120 mm Hg, and upon discharge cortate (7 mgm daily) was continued Two months postoperatively he was placed on $7\frac{1}{2}$ mgm of desoxycorticosterone acetate and supplemental salt A marked improvement was noted One month later 15 pellets of desoxycorticosterone acetate (percortin, each pellet containing approximately 125 mgm) were implanted and good results were obtained

After a period of 1 year his symptoms recurred and oral administration of adrenal cortical extract failed to completely alleviate the symptoms After readmission to the hospital, exhaustive studies revealed hypotension and calcification of the right adrenal gland Moderate improvement was noted with 5 mgm desoxycorticosterone acetate and 4 gm of salt daily Following stabilization and determination of extract requirements, 9 pellets of percortin (each pellet containing approximately 75 mgm) were implanted, and supplemental salt was given daily

PETER L SCARDINO, M D

Renal and Osseous Lesions (Reins et lésions osseuses)

J A LIÈVRE *J urol méd*, Par, 1949, 55 8

The relationships between the kidneys and osseous disease are numerous, for, without doubt, the kidneys are the principal organ of excretion of mineral substances stored in the skeleton Likewise, the kidneys destroy these substances and, conversely, by their alteration retain them in the osseous reservoirs

Parathyroid osteitis is due most frequently to a solitary adenoma of one of the parathyroid glands This tumor is not very large, about the size of a hazel nut, but it is large in comparison to the normal thyroid gland The disease is characterized clinically by painful bones with asthenia, and progressive demineralization of the bones along with various visceral signs The urinary signs consist of renal lithiasis, polyuria, and nephritic symptoms

The first symptom of lithiasis is frequently renal colic which is nearly always discovered within the first year or two years of the disease, that is to say, it is the symptom which suggests the diagnosis The author has seen this symptom in 3 of 4 cases In one of his patients a bilateral calculus that was visible on roentgen examination was the first sign of the disease Occasionally, the roentgenogram does not show a distinct calculus, but a diffuse milary calcification in the renal parenchyma is shown Renal colic without demonstrable calculi in the kidney or in the urine is due perhaps to the increased secretion of calculous material

Polydipsia and polyuria are interesting findings because they may be isolated symptoms of the disease

In 1931 Lièvre noted that a mild to moderate polyuria is frequently observed in parathyroid osteitis It may accompany the progression of the disease or be an early symptom of the condition

The signs of nephritis and renal insufficiency consist of albuminuria, cylindruria, hyaline or granular, and calcium phosphate casts in the urine Edema is rare It may be a part of the edema of late cachexia, or it may be associated with edema of the lower extremity accompanying the gross bone lesions Renal hypertension is rare while azotemia remains of moderate degree for a long time, but in late cases it leads to the fatal termination of the disease

A renal form of hyperparathyroidism was described by the author in 1931 In this form of the disease, the renal symptoms are the first that appear There are two phases of the disease, the one consisting of polyuria and the other of renal insufficiency The clinical history reveals the typical symptoms that are characteristic of hyperparathyroidism When urinary symptoms are present, one should search for other clinical signs of hyperparathyroidism The proportion of calcium, phosphorus, and phosphatase in the blood as well as the amount of urinary calcium should be determined If one of these elements is abnormal in amount, the blood protein should be measured and a search for osteoporosis should be made

The clinical signs of hyperparathyroidism may be inadequate to make a diagnosis If this is so, is it advisable to do a difficult exploration of the neck? The author believes that if the patient has a persistent hypercalcinuria, hypophosphaturia, and constant elevated blood calcium determination after five examinations, the operation should be done There were more than 30 cases in which the diagnosis was finally established at operation The mechanism of renal lithiasis in the course of parathyroidism and parathyroid osteitis can be explained as the result of transportation of calcium phosphate through the framework of the kidney and the precipitation of this substance from the saturated urine The precipitation takes place in the calices as well as in the kidney tubules Diffuse impregnation of the calcium takes place through the kidney, and in the advanced phase of the disease the calcium impregnates all the renal parenchyma Polyuria and pyelonephritis appear as an eventual consequence of the irritation of the mineral particles The impregnation of calcium easily explains the onset of sclerosis and renal insufficiency The polyuria may be due to the diminution in the concentrating power of the kidney, but it is more probable that it is due to the direct diuretic action of the parathyroid hormone

Renal colic and calculous excretions are observed frequently in the course of tuberculous osteoarthritis Coxalgia and Pott's disease are frequently associated with nephrolithiasis Roux, in 1937, discussed this subject He believed that the metabolic disorders, acid urine or urinary calculi, urinary infection, and excessive elimination are the causes of the lithiasis in cases of this type The author believes the cause to

GENITOURINARY SURGERY

be a general metabolic disorder, an osteoporosis, connected rather to the tuberculous lesion than to the immobilization of the patient. The "osteoporosis of immobilization," a term applied by American authors, is attributed to an absence of activity of the osteoblasts that have not recovered from the physiological stimulation that is usually present in the muscles and tendons. Renal colic and the passage of calculi are equally common in immobilization from other causes such as multiple fractures and serious fractures with prolonged immobilization, and in the course of infected fractures. Severe fractures of the vertebrae produce trophic changes in the kidney and motor disorders of the excretory passages.

Roux reported a case of renal lithiasis during the course of a severe gonorrheal rheumatism with diffuse osteoporosis. Mondor observed renal colic in the course of gonococcal coxitis, and Volkman saw this condition in a case of rheumatism immobilized for operative orthopedic correction. The author believes that all these conditions are osteoporosis of immobilization with excessive elimination of calcium phosphate by the kidney.

Osseous lesions are present in the disorders of calcium phosphate metabolism associated with chronic nephritis in the adult, but observations on this condition are not numerous due to the lack of research. There are, however, many clinical observations showing osteoporosis with destruction of the vertebral column.

In the young patient the osseous lesions are more apt to be secondary to the renal lesions (with azotemia, hypocalcemia, hypophosphaturia, and acidosis), but in the older patient a change in the bones is more frequent and the relationship between the renal and the bone lesion is more difficult to interpret. The role of the parathyroid gland in the course of chronic nephritis must also be considered, for the parathyroid gland may be hypertrophied in chronic nephritis. Perhaps the secondary hyperparathyroidism produces a vicious circle, with hyperphosphaturia and acidosis being a part of this cycle.

In the infant the osseous lesions can originate from the kidney. There is an arrest in the infant's growth with enlargement of the epiphysis, malformation of the knees genu valgum and genu recurvatum, and inflexibility of the diaphysis. When these signs appear, a search for renal insufficiency should be made. The patient may have polyuria of sufficient amount to cause one to think of diabetes insipidus. The urine is of low specific gravity and the kidney has lost its power of urinary concentration. Azotemia, which may be in an advanced stage before all these clinical signs appear, sometimes is found. Cylindruria is usually small in amount or absent. Euvolemia is usually small in amount or absent. The blood pressure is usually normal. The disease is fatal unless a curable lesion of the urinary passage is discovered since it has been proved that the secretory disorder is the cause for the disease.

The author describes the syndrome of Toni-Debre-Facot, a group of mysterious cases that present os-

seous lesions, osteoporosis, rickets, cessation of growth, and a renal type of glycosuria. The rickets is characterized by a final osteomalacic type of osseous degeneration. The glycosuria is more unusual since it is produced without hyperglycemia. The symptoms, with albuminuria, labile temperature, hypophosphatemia, disorders of amino acid and lipid metabolism are difficult to interpret. In certain cases hepatomegaly and visceral accumulation of cystine are found. It is believed that the syndrome is due to an anomaly of function of the renal tubules from which the glycosuria and perhaps the osseous lesions have their origin.

The author finally describes a morbid entity characterized by osseous lesions and a nondiabetic glycosuria. The bone lesions consist of zones of pseudo-fractures of the Looser-Milkman type with renal glycosuria. The glycosuria is probably due to an abnormality of the re-absorption of glucose and phosphates by the tubular mechanism of the kidney. The disease is thought to be due to the failure of the uriniferous tubules to form hexophosphate that is synthesized by the fermentation of phospholactate. The author describes the syndrome as consisting of a renal phosphoglucoside diabetes with the following characteristics: appearance in adults of painful bone lesions, asthenia, osteoporosis, fractures and pseudo-fractures of the Looser-Milkman type, fibrillations, and muscular tremors. The glycosuria is without hyperglycemia (a type of renal diabetes), phosphaturia is generally low, but at times there is an alkaline phosphaturia which may be high. The disease carries a grave prognosis.

CONRAD A. KUEHN, M.D.

Consideration of Paraneuritic Tumors (Considérations sur les tumeurs paranéphrétiques) HENRIQUE MANOEL A. RUPP *J urol méd*, Par., 1949, 55, 2.

The author defined retroperitoneal paraneuritic tumors as those neoplasms that have their origin in the retroperitoneal space. The origin of these tumors, whether from the fibrous capsule or the cellular adipose tissue around the kidney, cannot usually be determined before surgery or autopsy. The proximity of these tumors to the kidney and the urinary tract, with their effect upon the structure and function of the organs, thus presenting a diagnostic and therapeutic problem for the urologist. Because of the late symptoms associated with the growth of the tumors, they are usually discovered by mechanical urological disturbances.

The author reported 3 cases upon which the study is based.

Although these tumors are of various kinds, they are rare. Rupp reviewed the collected cases of various authors who studied 166 retroperitoneal tumors. In this group of cases there were 32 histological types. Because of this great variety in the histological classification of these tumors, the author suggested that they be studied more for in a general fashion there is no agreement.

authors concerning the pathologic findings associated with this type of tumor

The problem of recurrence is one of great importance in paranephritic tumors. Among the 3 cases reported by the author there was 1 recurrence. The 2 other cases had not been followed up long enough to determine if a recurrence would develop at a later date. During the first operation in 1 case the tumor was easily extirpated and the kidney was conserved. When the tumor recurred, its removal was very difficult for the kidney was involved and adherent to the wall as well as to the diaphragm. A nephrectomy was necessary. Ten months after the second surgical intervention the patient had a right subcostal mass that was very adherent to the pleura and no further operation could be done. The recurrence in this case could have been from the nodules that were undiscovered at the time of the second operation. It is almost impossible to remove all of the small nodulations that have the appearance of fatty tissue which is usually found in this region and completely clean out the retroperitoneal space. The nodulations may be the source of the usual recurrence of these tumors.

The recurrence may present a different histological structure from the original growth. In the author's case the primary growth was a neuroganglioma, and the recurrence was a histiosarcoma.

Many theories have been advanced to explain the etiology of these tumors. Haussmann and Budd, searching for an explanation of these tumors, drew upon the embryology and related each type of tumor to a stage in the embryological development.

In the embryo the genitourinary tract has an intimate relationship to the ectoderm. At the time the vertebrae and the muscles are formed, these structures are pushed forward. Following this movement, small nodules of ectoderm may be included. This may explain the future formation of tumors. This is the same idea suggested by the Cohnheim theory. These small fragments of embryonic cells always develop in response to unrecognized trauma or physiologic irritation. Lindenfied inoculated small pieces of mucosa of the pelvis and the ureters under the renal capsule. In 70 per cent of 25 experiments he obtained positive results. Solitary cysts of the kidney were formed in the area of these inoculated pieces of mucosa. He concluded from a genetic and clinical viewpoint that solitary cysts of the kidney differ only in their location and may be either intraparenchymatous, subcapsular, or pararenal.

It is almost impossible to determine the origin of these paranephritic tumors and their original location prior to autopsy or surgical intervention.

In discussing the symptomatology of paranephritic tumors the author quoted the classical description of Lecene. He described them as being abdominal tumors, developing slowly and progressively, unrecognizable or almost so, not producing a change in the general health for a long time, tumor hard or soft, possessing a lumbar location in the retroperitoneal region and in relationship to the intestine, and not

generally found except in relationship to diseases involving the urinary apparatus.

Roentgenological study is an aid in determining whether the tumors are intraperitoneal or retroperitoneal, and the relationship of the tumors to the neighboring organ is also of value in determining the possible surgical removal of the tumors.

The urologist is interested in the relationship of the tumors to the kidney and their influence upon the renal function. He is also concerned with the differential diagnostic problem created by these tumors and the best surgical approach for their removal.

A simple roentgen picture will show changes in the renal outline, a change from its normal position, elevation or immobilization of the dome of the diaphragm, and, in some cases, a concavity of the psoas outline. Windholz gives as a common sign a clear zone as compared to the surrounding tissue. This shows the existence of the tumor. Perirenal air insufflation demonstrates the renal shadow, especially the upper pole of the kidney. This is of value in outlining small suprarenal tumors and also the large tumors that surround the kidney, but there is the danger, more or less theoretical, of emboli or infection when this procedure is used.

Urography and pyelography are effective examinations in correctly revealing these paranephritic tumors. The kidney, a relatively mobile organ which is fixed by its pedicle, suffers many modifications of its position due to these retroperitoneal growths. This is shown by torsion of the kidney around its vertical posterior or horizontal axis. The location of the tumor is very important in the mechanism of this torsion. If the pedicle is short, the kidney remains fixed and is usually turned around on its pedicle, which produces a certain degree of rotation. If the pedicle is long, the mass may displace the kidney laterally and anteriorly downward.

The ureter, in general, is deviated laterally and anteriorly, inscribing an arc.

After urography, the relationship of the tumor to the abdominal contents should be studied by means of barium given by mouth and enema.

The diagnostic problem involves the location of the tumor mass, whether it is intraperitoneal or extraperitoneal. For the extraperitoneal mass, it is important to know whether it is a renal or a pararenal tumor. If it is pararenal, its origin, location, relationship to the kidney and other vital structures is important. It is necessary to make a clinical and roentgenological examination of paranephritic tumors because the diagnosis is always made by exclusion.

The subjective urinary symptoms are of little value because they are absent in most cases or come late in the course of the disease. Yet, they do serve as a means of elimination and exclusion.

Renal tumors, renal cancer, kidney cysts, hydro-nephrosis, and polycystic kidneys are eliminated from the diagnosis by the urinary symptoms they present and in addition they present a special roentgen sign in each case. Splenomegalia has a tendency

GENITOURINARY SURGERY

to develop inferiorly and to the inside, and on contact with the lumbar region shows a notched border. Cysts of the pancreas are rare, they are situated in the epigastric region and give typical alteration in the digestive tube. Cysts of the mesentery are in general movable, accompanied by partial obstructive symptoms and at times produce blood in the stools. Perinephritic abscesses, perirenal hematomas, chronic cholecystitis, and retroperitoneal appendicitis are eliminated by their modifications of the general health and by the acute character of their clinical course. A retroperitoneal tumor, even benign, causes death by cachexia or by compression of vital structures, and by its frequent transformation into a malignant tumor. These are the reasons for surgical removal.

X-ray therapy is used solely for inoperable tumors or as an adjunct to postoperative treatment. Its success depends upon the sensitivity of the tumor cells. X-ray therapy is of little value in lipomas.

Surgical treatment gives the best results, but there is some dependence upon the relationship of the tumor to the kidney and other vital organs. It is advisable to determine the renal function before surgical intervention, for it is frequently necessary to do a nephrectomy.

The principal difficulties encountered during surgery are those associated with freeing the tumor from the mesentery, aorta, vena cava, diaphragm, pleura, and the iliac vessels. The difficulties of surgery depend directly upon the relationship of the tumor and its size to its adherence to the surrounding structures and the difficulty in producing lines of cleavage. The surgical approach is usually transperitoneal. Franck employed the paramedian transperitoneal incision in 84 per cent of his cases. If one considers that the preoperative diagnosis is rarely made, the transperitoneal approach seems to be the best one. For small tumors on the internal border of the kidney or on the superior renal pole, and if the exact point of origin and adherence to the surrounding vessels is unknown, the author prefers the transperitoneal or the anterior lateral approach of Fey.

It is logical to suppose that the surgical approach depends upon the topography of the kidney. In the larger tumors a lumbotomy with the possibility of enlarging the incision above and below, with or without opening the peritoneum, seems the best operative incision. Various authors suggest different incisions, such as the lumboiliac and transverse incisions, but the choice depends upon the preoperative diagnosis and the relationship of the tumor to the surrounding organs. When the choice of the incision is lumboiliac or transverse, the peritoneum should be opened in order to inspect the abdominal content. After excision of the tumor, the retroperitoneal cavity should be carefully inspected so that small tumor nodules do not escape detection.

In conclusion, the author stated that a minute clinical and roentgenological examination of the urinary apparatus and gastrointestinal tract permits the preoperative diagnosis of retroperitoneal para-

nephritic tumors with relative ease. The anatomic relationship and the topographical location of the tumor give information concerning the surgical approach. A lumbotomy is indicated for the recognized tumors. The mortality is very high in spite of the technique employed. The most exacting treatment of this condition should be made in order to decrease the complications and permit the best prognosis.

CONRAD A. KUEHN, M.D.

The Problem of the Perirenal or Capsular Tumors of the Kidney (Zur Frage der perirenen Geschwulste—Nierenkapselgeschwulste) EWALD LEBBIN
Chirurg, 1949, 20: 10

Tumors of the retroperitoneum are often considered as one entity although this author and several others feel that they should be differentiated according to their origin. Although they all produce somewhat similar clinical pictures, those which arise from the perirenal tissues appear to have special significance. Included in the perirenal tissues are the structures which are enclosed in the renal fascia exclusive of the substance of the kidney and of the adrenal gland. Thus the tissues of origin are the fibrous capsule of the kidney and its few muscular fibers, the fatty tissue surrounding the kidney, and the fascial capsule which contains this structure.

The tumors of these structures appear to be very rare, Lubarsch reporting but one in a series of 30,000 to 40,000 autopsies. The author reports 4 cases observed in a period of 6 years in approximately 4,000 autopsies. The first of these they designated as a perirenal dysontogenetic fibromyolymphangiolioma with inclusion of pseudorenal canaliculi. The second case revealed a bilateral increase in the fatty tissue surrounding the kidney which was termed a tumor formation of the adipose renal capsule. The fourth case was one of a huge fibrolipoma of the perirenal area weighing 15 kgm., and 25 cm. in diameter. With exception of Case 4, all of the other tumors were found at autopsy and had not been subjected to clinical therapy.

WILLIAM C. BECK, M.D.

Tumors of Renal Pelvis (Ueber Nierenbecken tumoren) ALFRED GUETGEMANN
Chirurg, 1949, 20: 1

In the author's experience, malignant neoplasms of the renal pelvis are far more common than benign ones. Papillary tumors of the renal pelvis appear to have a tendency to grow down the ureter, and if this structure is not removed at the primary operation, they seem to recur in the ureter. Secondary removal of the ureter is often a most difficult procedure, and the dissection, which must be carried out to include the intracystic portion of the ureter, may be most difficult in cases of recurrence.

In the Urological Clinic, in Bonn, a surprisingly high percentage of renal pelvic tumors have been observed. In 13 of 88 cases, renal neoplasms were found. As in most series, these were largely in men in the fifth to seventh decade of life.

All of the lesions were diagnosed by the finding of unilateral hematuria and changes on either excretory

or retrograde urography. The latter is not without danger as in one case, it is believed, a ureteral metastasis was initiated by the retrograde catheter. The cystoscopic examination was important, not only in the finding of a unilateral hematuria, but also in revealing papillomatous material protruding from the ureter. Bleeding may be initiated by brisk palpation over the kidney, or by the catheter probe. The author states that any papilloma near the ureteral orifice should be investigated for the possibility of a similar tumor in the renal pelvis. The urographic study may reveal a filling defect, or an abnormal emptying of the renal pelvis.

(The pathological study of the tumor is of utmost importance. Serial sections may reveal that a tumor which appears to be benign in one area may be infiltrating in another. Certain of the seemingly benign neoplasms of this type may also show metastasis in the ureter so that clinically, at least, they are malignant.)

The authors find that in the case of tumor of the renal pelvis it is imperative to remove the entire ureter. In 21 cases which were followed up for a sufficiently long period, there were 20 recurrences, some years or even decades after the original operation. The treatment of recurrences with roentgen therapy or intraureteral radium is so poor that the author relegates it to the hopeless case.

Actually, however, the prognosis is not as bad as this might indicate. Of 12 cases followed over a sufficient period, 7 were alive and free of metastasis at 5 years, and 2 at 10 years. WILLIAM C. BECK, M.D.

BLADDER, URETHRA, AND PENIS

Biopsy and the End Results of Bladder Tumors
(La biopsia ed il destino dei tumori vescicali)
A. FRANCESE *Arch. ital. urol.*, 1948, 22, 417

Primary tumors of the bladder occur with moderate frequency. The most important, undoubtedly, are those which originate from the epithelium, and these, usually, are classed as villous tumors or papillomas.

Before the observance of these tumors by means of modern endoscopy for diagnosis and treatment, they were always considered of grave prognosis on account of the ease with which they recurred after they had been excised. Early diagnosis can now be made and electrocoagulation easily carried out under direct vision in the majority of cases, and in cases of recurrence the tumors can be combated with measures less serious than by attack through hypogastric incisions.

These tumors occur, usually, in middle age and more often in males than in females. They occur most frequently in the trigone. They may be single and develop in a circumscribed area of the bladder, or they may occur at many points and occupy a large area of the bladder.

In order to determine the clinical course of vesical tumors and in order to discover any agreement between the histological picture of the tumor at biopsy

and the postoperative course of the tumor, the author carefully studied 101 vesical tumors which were treated in the Tumor Clinic of Turin during the years from 1936 to 1946.

The cases observed were divided into three large groups. The first group consists of those cases in which there was an exact agreement between the microscopic report of the biopsy and the postoperative course. In the tumors of the second group of cases there was an exact disagreement between the biopsy and the postoperative clinical course, and in the third group the biopsy report was doubtful.

In the first group there were 64 cases, in 28 of which both the biopsy report and the postoperative course showed the tumor to be benign, while in the remaining 36 cases, both the biopsy report and the postoperative course showed the tumor to be malignant.

In the second group there were 19 cases, in 3 of which the biopsy showed that the tumor was benign and yet the postoperative course was that of a malignant tumor. In the remaining 16 cases, the biopsy showed that the tumor was malignant and yet the postoperative course proved it to be benign.

In the third group there were 18 cases in which the biopsy was doubtful. In 10 of these cases the postoperative course was that of a malignant tumor and in 8 the postoperative course showed that the tumor was benign.

The first group was comprised of the largest number of cases. The 28 cases which appeared benign at biopsy followed a benign postoperative course following biopsy. In those cases in which the new growth appeared somewhat extensive and infiltrating, partial resection was performed, and the area excised was studied and found to have atypical structural characteristics in perfect accord with the histological preparation made at the time of biopsy. In this group the most interesting evidence produced was the preponderance of the malignant form of the tumor over the benign type. This is in agreement with the statistics of other authors.

In the second group, several facts are to be considered to explain the discrepancy between the biopsy report and the clinical course after operation. In cases in which malignancy was not revealed by the first biopsy, it is probable that on account of the numerous villous processes of the tumor a section of the base of the tumor which might have shown the malignancy was not included in the specimen removed. After electrocoagulation following biopsy, the thickness of the tumor was lessened and the base of the implant was more easily accessible and included in subsequent biopsy sections. Characteristic invading malignant cells were then demonstrated in the connective tissue stroma. In those cases in which the biopsy was malignant and the postoperative course was benign, the apparent discrepancy is explained by the fact that the malignant tumor was completely removed by the initial electrocoagulation therapy. When a second biopsy was taken later, the biopsy tissue appeared normal and

GENITOURINARY SURGERY

contained no signs of the pre-existing tumor because it had been thoroughly destroyed.

In the third group of cases, in which the biopsy was doubtful at the initial examination, the biopsy was repeated two or three times without revealing absolute proof that the tumor was benign or malignant. In the doubtful cases in which the postoperative course proved to be that of a benign tumor, it is probable that any malignancy that might have been present was in the initial stage and was completely destroyed by the electrocoagulation treatment following biopsy. In the doubtful cases in which malignancy was not proved until after repeated biopsies, the discrepancy is explained by the fact that a portion of the base of the tumor showing atypical cells was not included in the biopsy specimen. The malignancy in the tumor persisted in spite of repeated electrocoagulation treatments.

From these interpretations, the importance of obtaining a portion of the base of the tumor in a biopsy section is made evident. Sufficiently large pieces should be taken from different parts of the tumor, care being taken to avoid necrotic areas. A careful and painstaking histological technique should be employed. Repeated biopsy examinations at 2 or 3 month intervals should be carried out in cases of persistent or recurrent tumors to avoid overlooking possible malignant tumors and to determine the need of extensive electrocoagulation therapy.

BLACKWELL MARKHAM, M D

GENITAL ORGANS

Retropubic Prostatectomy R LICH, JR, O GRANT, and J E MAURER *J Urol* Balt, 1949, 61 930

The authors present a comparative study of 65 retropubic and perineal prostatectomies, both of these operations are extravascular surgical procedures. They note that Millin's technique of retropubic prostatectomy has been received in the United States with interest in spite of the adverse criticism accorded similar techniques by Von Steckum in 1909, and by Jacobs and Casper in 1933. The authors believe that the antibiotics of today have afforded the necessary surgical courage to invade the vulnerable space of Retzius. They describe the radical anatomy, and both the conservative and radical retropubic techniques of prostatectomy. The operations are well illustrated.

The average age of patients undergoing perineal prostatectomy was 68.8 years, the age of those having the retropubic prostatectomy was 68.1 years. Vesical catheter drainage averaged 10.1 days in cases of perineal, and 6.0 days in cases of retropubic prostatectomy. In the last 26 retropubic operations, the catheter was removed earlier, which reduced the average period of drainage to only 4.9 days. The postoperative sojourn for the perineal operation was 17.9 days as against 12.3 days for the retropubic operation, patients having the latter operation experienced a more comfortable and more active postoperative convalescence. Forty-three (66.1%) pa-

tients in the perineal group required blood transfusions while only 8 (12.3%) patients of the retropubic series required blood replacement. In the retropubic series the average postoperative period necessary before the urine was microscopically (not culturally) normal was 31 days, while in the perineal group this result was accomplished in 27 days. Seven patients of the perineal series suffered temporary stress incontinence of less than 19 days and another patient suffered incontinence of almost 3 months' duration, while in the retropubic group there were only 3 instances of stress incontinence (in 2 cases, 5 days and in 1 case for more than 2 weeks' duration). Latent hemorrhage occurred in 2 patients of the retropubic group, while bleeding occurred once in the perineal group. There occurred one instance of suprapubic fistula in a patient with an unusually large diverticulum following the retropubic technique. Chondritis of the symphysis pubic occurred twice in the retropubic, while none was seen in the perineal group.

The incidence of cancer of the prostate in the perineal series was 8.2 per cent, in the retropubic series cancer was observed in 5.1 per cent. Radical retropubic or perineal procedures were carried out when the diagnosis of cancer was made at operation. In 3 cases of the retropubic series, cancer was unsuspected and was revealed after histologic examination of the specimen, it seems to be more difficult to detect carcinoma during the retropubic than during the perineal prostatectomy. This fact seems to constitute a distinct disadvantage of the retropubic operation.

One death occurred among the patients who had perineal operations. There were no deaths in the retropubic series.

Retention of potency after retropubic prostatectomy is high and it approaches that of transurethral resection, while impotence is the rule after perineal prostatectomy. ROBERT TURELL, M D

Varicocele RAYMOND O OLSON and ERIC P STONE. *N England J M*, 1949, 240 877

The authors present a critique of the varicocele syndrome and the results they obtained from a new operation done on 25 patients. The pathologic physiology was reviewed and attention was drawn to the concept of dual venous drainage of the deep and superficial systems (Fig 1).

The clinical picture was described in detail. It was stated that a coexistent hernia may be present in 25 per cent of the cases. In most instances it is possible to evaluate the symptoms and to establish whether they are due to the varicocele, a coexistent varicocele and hernia, or to one of the ill-defined syndromes of orchialgia or chronic epididymitis.

Of therapeutic importance is the fact that the textbooks have as yet not assimilated the new literature and still offer a pessimistic outlook. Usually the symptoms are ascribed to overcongestion from unfulfilled sexual desires, scrotal fixation in psychoneurosis, and other poorly defined causative factors.

Fig 1 (Olson, Stone) Diagram of the venous drainage of the scrotal contents (adapted from Javert and Clark). Primary system—internal spermatic, ductus deferens and external spermatic veins (in white). Secondary system—superficial epigastric, superficial internal circumflex and cremasteric veins, and, through scrotal tributaries, the superficial and deep pudendal and the internal pudendal veins (in black).

As a consequence, surgery is considered unwise. The authors took issue with these views and pointed out that the role of psychoneurosis in this condition has been overemphasized and the pessimistic attitude toward surgical treatment is not warranted. They pointed out that a patient with typical varicocele symptoms can be effectively relieved by the high ligation technique which is attended by very little risk of operative complication, the low ligation operative procedure has been abandoned.

The technique of the high ligation procedure is as follows:

Through an oblique inguinal incision the external oblique fascia is split through the external ring to allow better exposure and a more effective herniorrhaphy. The spermatic cord is completely freed to the level of the internal ring. It is believed that this step allows for better eventual testicular suspension. The cremasteric fascia is opened longitudinally, and the internal spermatic vein isolated. Usually, one large vein, approximating a pencil in size, is found and is ligated at the internal ring, as is a secondary smaller vessel if present. In this series 15 patients had one vein, and 10 presented two veins which in all cases were found to anastomose retroperitoneally. A segment of the vein from 2 to 5 cm in length is excised, and the proximal end is allowed to retract retroperitoneally. Careful search is then made for a hernial sac. If found, it is dissected free, and the sac is ligated. Testicular suspension, which is next carried out, is

considered very important for the final result. Three techniques are followed: the distal vein stump is pulled proximally and sutured through the cremasteric fascia to the internal oblique muscle, the cremasteric fascia is closed transversely, and a further tightening of the lax spermatic cord is obtained by suture of the conjoint tendon under the cord to the shelving inguinal ligament. This lifts the cord by the mere presence of tissue beneath it. The external oblique muscle is then resutured above the cord. Silk suture material is used throughout the procedure. Postoperatively, the patient wears a suspensory for 2 weeks. He is allowed to be ambulatory on the first postoperative day and is eligible for discharge on or after the sixth postoperative day.

ROBERT TURELL, M D

Malignancy in Cryptorchidism WILLIAM A CARROLL, *J Urol*, Balt., 1949, 61: 396

Recapitulation of the reported incidence of cancer in cryptorchidism reveals a marked variance in submitted statistical analyses and conclusions. To study the problem, the author submitted a questionnaire to each active and associate member of the Western Section of the American Urological Association and to each member of the American Urological Association.

An examination of the statistics, which showed a high incidence of cancer in cryptorchids when compared to the incidence of undescended testes in general, revealed a similar pattern was followed in assembling the data: (1) individual series with a small number of malignant tumors, (2) compilation of reported series supplemented with estimated or hypothesized figures from reliable sources for the missing data required for statistical purposes.

Four groups of figures were necessary for either of these two approaches to statistical tables: (1) total male hospital admissions or estimated total male population, (2) total or estimated total number of patients with malignant testicular lesions, (3) total number of patients with cancers in undescended testes, (4) total or estimated total number of patients with undescended testes.

A careful consideration of these four prerequisites to the statistical tables revealed numerous assumptions, estimations, and, according to the author, fallacious conclusions. It was apparent that the subject did not lend itself to acceptable statistical review. Hence the author submitted his questionnaire.

Of the 662 replies, 76 per cent of members of the American Urological Association and 81 per cent of members of the Western Section of the American Urological Association had never seen a malignant undescended testis. One hundred and twenty-six members of the American Urological Association and 33 members of the Western Section, American Urological Association, reported a sum total of 285 malignant tumors in cryptorchids seen by them.

On the basis of this study, the author concluded that malignant testicular tumors are rare, cancer in cryptorchidism is still more rare and should be class-

GENITOURINARY SURGERY

ified according to its anatomical location, the incidence of cancer in cryptorchidism from the actual cases reported is so minute that the malignancy potential cannot be used as an indication for either orchidopexy or orchiectomy PETER L SCARDINO, M D

Streptomycin in Urogenital Tuberculosis A C ABERNETHY and H H EDELBROCK *J Urol*, Balt., 1949, 61 410

Ten patients with genitourinary tuberculosis who had failed to respond to other forms of therapy were treated with streptomycin. The findings in these cases are submitted by the authors as a preliminary report. The effectiveness of streptomycin having been demonstrated both in vivo and in vitro, the authors were stimulated to use streptomycin as an adjunct to other accepted forms of therapy. The therapeutic regimen consisted of the administration of streptomycin, 0.3 gm intramuscularly every 3 hours with a maximum total dosage of 400 gm, 1 dram of choline chloride daily, when tolerated, and surgical removal of the tuberculous organ when possible.

Ten cases of genitourinary tuberculosis were reported in detail. Under treatment, 3 tuberculous sinuses closed. Of the 4 patients with apparent renal tuberculosis, 1 patient was treated surgically, in 1 the process appears to be arrested, 1 is definitely improved, and the fourth patient expired. There were 3 patients with involvement of the ureter. One of these died, and autopsy showed that no healing had taken place, in 1, the ureter was removed, and in 1 the ureter appeared normal by excretory urogram following therapy.

Of the 7 patients with tuberculous cystitis, 1 died and showed no evidence of healing, in 4 the process (cystoscopically) appeared arrested, and 2 were subjectively improved.

In 2 patients with testicular tuberculosis in a solitary remaining testis, there was evidence of arrest of the process.

It was difficult to evaluate the response of tuberculous prostatitis to the therapy employed, however, all patients were clinically improved. Pyuria cleared in 7 patients, was improved in 1 patient, and was unchanged in 1. None of the patients had been followed more than 20 months.

On the basis of this experience, the authors conclude that streptomycin will produce improvement in the general status of the patient and clear the urine of tubercle bacilli, albeit a temporary effect. The use of choline chloride is not well understood. The toxic effects of the therapy were relatively minimal. All patients developed transient dizziness. One patient sustained some hearing loss and another, destruction of vestibular function.

PETER L SCARDINO, M D

Urinary Tract Calculi J C KIMBROUGH and J C DENSLOW *J Urol*, Balt., 1949, 61 837

The authors discussed the incidence, etiology, diagnosis, and treatment of urinary calculi occurring in 15 recumbent patients with bone injury, as observed at the Walter Reed General Hospital, Washington, D C. During the period of investigation of these patients, there were about 800 other hospitalized patients who had been immobilized for long periods of time because of bone injury. A great many of these patients had suffered injuries during the past World War. The shortest period noted for calculi formation was 74 days and the longest period was 1,200 days, with an average of 362 days or mean time of 272 days. Etiologically, urological infection was not important, but a reduced fluid intake, urostatics, and focal infection (osteomyelitis) were of great importance.

The long period of immobilization required to produce urolithiasis suggests that the condition may be due to damage of the renal epithelium by some prolonged active process or disturbed calcium metabolism.

Proper prophylactic care against the formation of urolithiasis is outlined in some detail, but the authors stated that it is difficult to carry out an adequate regimen of fluid intake, diet, movement, and chemotherapy for all immobilized patients in a large service such as theirs. The authors believe that good results are possible if patients susceptible to urolithiasis are selected and preventive measures are applied.

The preferred treatment of these calculi is removal by dissolution or spontaneous passage. Caution is exercised during manipulative procedures. When these measures fail, operative therapy is instituted without further delay.

ROBERT TURELL, M D

The gross form of a part seems to have an intrinsic determinant, but in later development of the limb is increasingly affected by extrinsic factors and reciprocal adaptation. An inherited alteration in timing or an environmental interruption in the tempo of operation can readily be related to defects in a constantly changing structure.

Minute study of normally developing embryos from 8.5 millimeters to 53 millimeters shows an orderly and rapid adaptation of undifferentiated mesenchyme into the structure characteristic of the mature hip joint. This makes incredible the concept that the posterior superior border of the acetabulum fails to form normally because of an inherited defect in one bit of this mesodermal mass.

Hereditary and extrinsic factors can surely alter the normal rate of growth and interfere with chronological development by delay or stimulation of growth. Adaptive variations to pressure and position recognized in postnatal growth must admittedly be even more potent in the more rapid tempo of early prenatal growth. The recognized deformities characteristic of congenital dislocation of the hip, i.e., a shallow socket, enlarged head to fit it, increased anteversion, and subluxation can all be logically accounted for by following through these basic facts. Study of the "healthy side" in a large group of unilateral dislocations showed pathologic changes in 80 per cent of these so-called normal hips, which strongly suggests that the defect is not isolated to one hip but is of the pelvis as a whole.

The author believes that congenital dislocation and congenital dysplasia of the hip may be regarded as the result of faulty development due to environmental factors extrinsic to the hip joint. An inherited fault in the timing of development may produce these extrinsic changes. Interference with the normal dynamic reciprocal relationship of the hip joint components may produce the secondary adaptive changes which lead to this deformity. The known embryology of the hip joint refutes the theory of primary inherited failure of development of a part of the acetabulum. FRANCES E. BRENNER, M.D.

The Morphology of Congenital Coxa Vara (Zur Morphologie der Coxa vara congenita)

LINDEMANN *Zschr Orthop*, 1948, 78: 47

Congenital coxa vara is not a disease entity. It is a hypoplastic malformation of the skeleton. There are 2 types: the primary type develops in the fetal period and may lead to large defects of the femur; the other type develops in infancy and is caused by an inherent weakness or hypoplasia of the subcapital epiphysis, greater trochanteric epiphysis, and ischio pubic epiphysis. This deformity was observed in 2 twins.

Primary congenital coxa vara was observed in a 19 months old boy whose only complaint was a limp favoring the affected extremity. The roentgenogram showed absence of the ossification center in the femoral head of the affected side, with flattening of

the acetabulum, and thickening of the femoral neck, but no dislocation. Another child, 6 months old, showed shortening of the femur, clubfoot, and flattening of the acetabulum and the proximal upper femoral epiphysis on the same extremity. Roentgenograms were taken every year and at the age of 12 the appearance of the originally deformed hip was essentially normal. The treatment consisted only of continuous nonweightbearing on the affected side. The author points out that primary coxa vara congenita may heal spontaneously.

GEORGE I. REISS, M.D.

Congenital Dysplasia of the Hip Joint Relationship Between Congenital Subluxation and Congenital Dislocation

Bone Surg, 1949, 31-A: 357

Congenital subluxation of the hip, as a distinct entity, has not been recognized in America as clearly as in Europe. The problems of congenital dysplasia of the hip are made clearer by an understanding of the pathogenesis of subluxation.

If in fetal life a shallow socket forms, or there is a primary dysplasia of the acetabulum, five possibilities for the future of the hip joint are present: (1) complete dislocation, (2) incomplete displacement between the femoral head and the flat socket with some articular contact persisting and without capsular interposition—the entity under discussion, (3) no displacement between femoral head and the shallow acetabulum, (4) a rare, extreme dysplasia and general malformation of hip structures, (5) the dysplastic hip displaying the rare phenomenon of spontaneous recovery.

Acknowledging the varying potentials for recovery or repair inherent in the dysplastic hip, the most important factor in influencing treatment is that of age. A favorable mechanical and functional position obtained and maintained before weight-bearing prevents secondary pathological changes. At this early age, subluxation is common, and dislocation rare. Subluxation often persists throughout life as an entity, and often coexists with dislocation of the opposite hip. These conditions possess a common etiology.

Residual subluxation exists in a hip previously dislocated, when only partial replacement of the head in the acetabulum is secured by open or closed manipulation.

Not all congenital displacements of the hip should be explained by a single mechanism. The author limits his study to those caused by aplasia (of genetic origin) of the posterior superior portion of the acetabulum. Other structures of the hip joint may share in the dysplasia. The sequelae are explainable on the basis of laws of bone growth, aseptic necrosis, and traumatic osteoarthritis.

A review of the literature presents evidence that many authors have recognized subluxation as a state distinct from classical dislocation of the hip, and not just as its precursor. Familial tendency to affections of the hip in this category is well known, but less

regularly has dysplasia of the "well" side been recognized in a child with a unilateral dislocation. Frequently symptoms referable to the dysplasia do not appear until adolescence or early adult life. The advanced osteoarthritis of middle age is frequently secondary to a hitherto "silent" subluxation.

Residual subluxation, i.e., incomplete reduction of a dislocated hip, remains a fixed condition especially because of the inadequate acetabular roof. The trauma of instability over the years leads to osteoarthritis roentgenographically identical with that present in congenital subluxation.

Faber, in 1937, reported studies on patients and families which led to his concept of a hereditary defect in the joint, common to dislocation and subluxation.

Surgical exploration of the hip in children under 4 years of age shows a high incidence of subluxation, with some portion of the head of the femur in contact with articular cartilage of the acetabulum.

FRANCES E. BRENNKECKE, M.D.

The Synovial Membrane of the Knee in Pathologic Conditions ROBERT SOEUR *J. Bone Surg.*, 1949, 31-A, 317

The gross changes of color and consistency in synovial membrane are familiar to all surgeons who open knee joints, but the pathologic changes and etiologic factors of these changes can only be determined by microscopic study.

Numerous studies have contributed to the now accepted facts that synovial membrane is (1) mesenchymal in origin, (2) active primarily in a manner similar to reticuloendothelial tissues, and (3) able to adapt morphologically to varying mechanical or pathological conditions.

The histological classification of Key, based on the nature of subjacent layers rather than on surface morphology, is adopted by the author, i.e., adipose type of synovium over articular fat pads, fibroareolar type where pressure and pull predominate, and fibrous type of synovium over tendons and ligaments. The author adds a muscular type covering the suprapatellar pouch. Studies have been based on biopsy of the infrapatellar fat pad which is affected early by pathologic change, and is readily accessible.

The histology described by Key was confirmed in the normal human and rabbit and is well illustrated in photomicrographs. Studies were then carried out in man and rabbits in three joint conditions, i.e., ruptured menisci, hemarthrosis, and chronic hypertrophic villous arthritis. The literature is extensively reviewed in each instance. Excellent photomicrographs follow the tissue changes over a long period of time in each instance. The histological changes observed in man are closely reproduced in animals experimentally by the use of irritants comparable to those initiating similar states in man. The descriptive terms used in evaluating these tissue changes are defined as follows: "synovial activity" means an increase in number and importance of folds and villi, irregularity of the free border and

desquamation, multistratification of the intima, disappearance of the adipose vesicles of the external layer and appearance of collagen bands, and sclerosis of vascular walls. "Infiltration" is defined as multiplication of free cells (normally rare), and appearance of new circulating cells. Using these terms, the changes arising in the synovial membrane in the presence of meniscal tears are mechanical, continuous, and progressive, with fibrosis predominating. In hemarthroses, the changes are of a chemical nature (endogenous proteins), rapid but short-lived, with early return to normal tissue. In villous arthritis, the phenomenon of Arthus is reproduced in a joint, therefore, an allergic response occurs intensely, diffusely, and over a long period of time.

These changes are so characteristic that biopsy of the infrapatellar fat pad is suggested as a precise means of establishing the etiology of a morbid process in the knee.

FRANCES E. BRENNKECKE, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Further Studies in Articular Replacement STEPHEN S. HUDACK and J. WALLACE BLUNT, JR. *Am. J. Surg.*, 1949, 77, 600

About ten years ago the authors attacked the problem of joint replacement on an experimental basis. Since fixation of replacement elements to bone causes stress concentration, and thus bone and tissue death, a new diffuse method of fixation of the stress-bearing elements was tried. A dynamic relation of the replacement element and the host tissue was achieved in dogs, and the idea of joint replacement without fastening at any specific points was feasible.

The text and illustrations demonstrate a type of internal prosthesis to be used in replacing the femur proximal to the subtrochanteric area and the humerus in its proximal third. An acrylic plastic model is made from dimensions gained from the patient's roentgenograms. This model is firmly attached to a long metallic intramedullary nail.

The operative technique and certain principles are explained. Wide excision of the whole synovial lining of the hip joint is stressed in order to denervate the joint and obtain a painless joint. Tendinous attachments about the trochanters are left attached to a shell of bone. Special attention to the intramedullary canal and the relation of the prosthesis to the general limb alignment are important.

Five cases of hip replacement are reported. In 1 case operation was performed for the correction of aseptic necrosis following nonunion of a femoral neck fracture. In another (bilateral) case, operation was done for Marie-Strumpell spondylosis with ankylosed hips. In 2 cases operation was performed for arthritic disease of the hips. The prosthesis was used in one hip to replace resection for chondrosarcoma. The single humeral prosthesis was used to replace resection for chondroblastoma.

The patients are reported to have gained acceptable joint motion with considerable relief of discom-

fort In most instances, patients were followed up for less than 1 year, therefore the present report is not intended as an end result study. Speculation is made as to just what will happen in time, for example, in regard to acetabular changes.

KENNETH H. SPONSEL, M.D.

Arthroplasty of the Elbow Joint (Eine Studie ueber die Plastik des Ellenbogengelenkes) A VOGL

Zschr Orthop, 1948, 78 21

In the 8 cases in which arthroplasties of the elbow were done the following criteria were followed: The patient must be young, the muscles about the elbow must be intact and able to move the elbow joint, and there must not be an infection of the bones close to the elbow joint.

A semicircular incision was made from 3 to 4 cm above the olecranon. The triceps muscle was cut along a line from a lateral point above to a medial point below. The olecranon was dissected free from the humerus. The head of the radius was excised. The distal end of the humerus was shaped into a wedge to leave the lateral and medial sides intact. The space between the olecranon and the humerus was kept fairly large. A thin layer of tissue found between the fascia proper and the subcutaneous tissue was placed between the bone ends, the fatty side being turned toward the gliding surfaces. Fatty tissue is less likely to be destroyed by lack of oxygen, and therefore there is less chance of necrosis when this tissue is used than when fascia is used. The triceps is resutured with its ends slightly apart. The drains are removed between the third and eighth days and the cast is removed on the fourteenth day. The physical findings and roentgenograms of the 8 arthroplasties are presented. The results were uniformly good.

GEORGE I. REISS, M.D.

Tendon Transfers and Arthrodeses in Combined Median and Ulnar Nerve Paralysis J WILLIAM LITTLER

J Bone Surg, 1949, 31 A 225

Injuries involving both the median and ulnar nerves may result in great functional loss. Excellent extrinsic muscle function and good sensation may return after nerve suture, but the hand frequently is clawed and rendered almost useless through the loss of thumb opposition and finger extension. The pulp atrophy which often accompanies nerve injury is a severe disability and makes the already impaired pinch mechanism ineffectual.

This article demonstrates how the deformity can be overcome partially by appropriate tendon transfers and arthrodeses designed to restore muscle balance and to bring the thumb and fingers into a functional position. An effort has been made to simplify the transfer of the tendons, as it is impossible to compensate for all the complex intrinsic muscle functions. Frequently only the most important intrinsic functions can be considered.

The various tendon transfers and arthrodeses are discussed in detail. Correct evaluation of the par-

tially paralyzed hand must be made and available tendon power must be concentrated where it will be effective in restoring useful function. Proper arthrodeses will provide stabilization and make additional power available for transfer. Not infrequently, it is necessary to fuse the wrist or the thumb, or both, in a position of function, and to transfer wrist extensor tendons if a good pinch and grasping mechanism is to be gained. In badly crippled hands only a pinch mechanism may be possible, but to that end we should concentrate our effort, if we attempt more, potential power may be dissipated and a useless hand will result.

The article is accompanied by excellent photographs and drawings and contains many important practical considerations.

RUDOLPH S. REICH, M.D.

Pinning for Slipping of the Epiphysis of the Femoral Head GUNNAR WILBERG

Acta orthop scand, 1948, 18 4

The present report is based on 38 cases of slipped epiphysis. In these patients, the condition was considered mechanically suitable for pinning with a flanged nail, as a method of maintaining position. Thirty-six hips were pinned without previous reduction, one required closed reduction and another required open reduction. Necrosis of the head occurred in 2 cases (one in which closed reduction had been done), and fracture of the femur secondary to the pinning occurred in 2 cases.

The author theorizes that changing the position of the nail and adding trauma to the femoral head may contribute to the development of aseptic necrosis. He believes also that the nail should not be driven deeply into the epiphysis, but should just enter the epiphyseal cartilage, thus causing minimal injury to the circulation of the epiphysis.

The increased burden on the opposite, unaffected hip has been considered a factor in producing slipping on that side also. This occurs in 15 to 25 per cent of cases. The author permitted early weight-bearing on the side operated upon and thereby spared the "well" hip. In a series of 24 cases, the opposite hip was involved in 20 per cent, suggesting that the increased burden is unimportant.

The author believes that gentleness in reduction is very important and that open reduction may be less traumatic than closed reduction. An excellent result was obtained in his 1 case of open reduction.

NEWTON C. MEAD, M.D.

Open or Bloodless Treatment of Clubfeet (Blutige oder unblutige KlumpfuB Behandlung) ARNOLD SONNENSCHNEIN

Acta orthop scand, 1949, 18 266

Early treatment of congenital clubfoot is essential for success. Only occasionally is an elongation of the Achilles tendon necessary. As a rule, adequate mobilization in a plaster of paris cast, followed by proper aftertreatment, produces in children a normal foot, but leaves a certain degree of deformity in adults. Therefore open operation is indicated only when other measures fail.

The treatment of clubfeet in infants consists of passive motions, namely, correction of the supination of the posterior portion of the foot, of abduction of the anterior part of the foot, and of the equinus position. Following correction, a flannel bandage is applied to the feet in a position of pronation until the next exercise. The treatment is instituted during the second week of life. A plaster of paris splint is applied in the sixth week, and 2 weeks later, after a greater correction of the faulty position of the feet, it is replaced by another splint. The splints are removed three times a day to allow passive exercises. A "redressment" is done in the third month of life. A manual stretching of the soft tissues brings the subluxated bones into proper position.

The astragalus can be reached only indirectly by action on the os calcis. The equinus position is temporarily disregarded. The cast remains in place 3 months. After removal of the cast an overcorrection is accomplished and an elongation of the Achilles tendon, if necessary, is obtained by tenotomy.

The author usually employs the subcutaneous section of the tendon in an oblique direction. The second cast is applied for 3 months.

After removal of the cast, splints are worn for 1 year and after that orthopedic shoes are used up to the sixth year of life.

In adults the manual treatment of clubfeet is followed by redressment and employment of an osteoclast. The manual redressment over a wooden wedge is followed by the application of a cast. After 2 months the osteoclast is used and a subcutaneous oblique tenotomy of the Achilles tendon is performed. The foot remains in the second cast from 3 to 4 months, after which time the patient begins wearing an apparatus or an orthopedic shoe.

Of 152 patients treated by the author, 108 were younger than 1 year. The results were perfect in 76 infants, satisfactory in 23, and unsatisfactory in 9.

The results were satisfactory in 32, and unsatisfactory in 12, of 44 patients from 15 months to 35 years old.

JOSEPH K. NARAT, M.D.

Operative Treatment of Clubfoot in Older Children and Adults. HENRIK STÖREN. *Acta orthop scand*, 1949, 18: 233.

The author draws upon his own experience and that of others in the formulation and execution of the method he uses to correct the severe neglected clubfoot. He disapproves of one-stage operations which often lead to partial gangrene or poor correction, and he believes that extensive wedge resection in the bony operation leads to a short, distorted foot. Another firm conviction is that the apparent inward torsion of the tibia in patients with clubfoot is really inversion of the calcaneus on the talus. When this apparent torsion persists after surgery, he believes that the inversion of the calcaneus was not corrected at surgery.

His program is carried out in two or three sessions with soft-tissue correction preceding the final stage bone operation. In this manner, he is able to keep

bone removal to a minimum, and thereby maintain all possible foot length.

The first stage is the soft-tissue operation on the medial side of the foot and leg. This includes division of the contracted fascia and ligaments, the plantar aponeurosis, and the posterior insertion of the plantar muscles. The tibialis anterior tendon is divided preparatory to transplantation to the dorsum of the foot, since it has become an adductor in the deformity. A longitudinal incision is made medially in the lower leg, and the tibialis posterior tendon and the flexor tendons are lengthened. This wound is then closed. It is necessary to fashion a flap or a double-end sliding graft to cover the operative wound on the foot and, in a few days, the skin defect more dorsally is covered with a Thiersch graft through a window in the cast. Calluses and bursae are not removed, since they disappear spontaneously.

The second stage of the operation is performed in about 4 weeks. The Achilles tendon is lengthened with preservation of the lateral calcaneal insertion, and other soft tissues are divided. The changes in the relative sizes of the contacting talus and the malleolar cleft may offer resistance to dorsiflexion which cannot be corrected in this operation. The heel is pulled down by means of a wire through the os calcis. This may be incorporated in the plaster or may be utilized for continuous traction, as required. A residual 10 to 15 degrees of equinus due to bony ankle deformity is overcome in the final bone operation. At this stage the posterior processes of the os calcis may be found underdeveloped. With correction of the equinus, the tibialis anterior tendon is transplanted to the base of the second or third metatarsal.

The final stage of frontal and horizontal wedge osteotomy is performed 4 or 5 weeks later. The exposure of the tarsal joints is accomplished without division of the peroneal tendons. The frontal wedge is taken into, or anterior to, Chopart's joint and, similarly, the horizontal wedge in or below the talo calcaneal joint. It does not seem to matter whether one does a full arthrodesis or takes the wedge outside the joint, provided the chiselling is in the right place and is sufficient to obtain full or slight overcorrection. For the equinus position which still remains, the wedge osteotomy of the calcaneus is made broader anteriorly and the frontal wedge is correspondingly adjusted. In this way the equinus foot is corrected without producing the rocking foot.

Twenty-one clubfeet in 15 patients have been operated upon by this method. Several series of photographs are included to demonstrate the principles of treatment. Follow-up examinations are made up to 8 years and the results appear most satisfactory, in fact, the preoperative and postoperative illustrations are quite striking by comparison. After correction, all patients wore ready-made factory shoes.

In the discussion, the author mentions two deformities that are not influenced by this operation.

first, in some cases a compensatory valgus position at the ankle joint may lead to an arthrosis, secondly, atrophy of the posterior calcaneal process may lead to difficulty in keeping shoes on, and less often to insufficient weight-bearing surface of the heel

KENATH H SPONSEL, M D

wire at each end being necessary Torsion, dislocation, or fracture of the graft is prevented by this method Furthermore, the transplanted bone need not be nearly as long as in grafting without nailing The routine procedure is to make the transplant long enough to assure an area of contact between the graft and the fractured bone of 4 cm at each end In many cases this causes a considerable defect in the tibia from which the graft is taken If, however, the graft is supported by an intramedullary nail, a much shorter plane of contact is sufficient to secure correct healing

Also in cases in which pseudarthrosis is not due to bone defect but to poor alignment, intramedullary nailing gives excellent results In appropriate cases percutaneous nailing is possible, this avoids the dangers of open bone work which are especially great in war wounds

WERNER M SOLMITZ, M D

Removal of the Base of the Proximal Phalanx in Hallux Rigidus ERIK SEVERIN *Acta orthop scand*, 1948, 18 77

The author reviews a series of 37 operations in 31 patients after a period of 3 to 8 years following surgery All of the patients had suffered from hallux rigidus, and all were operated upon by the same procedure The operation consists of the removal of from one-half to two-thirds of the proximal longitudinal of the proximal phalanx through a medial longitudinal incision An osteotomy is made at right angles to the phalanx, and no periosteum is left in the area of resection The surface of the metatarsal head is then trimmed, and all hypertrophic exostoses, except on the plantar surface, are removed A small, soft tissue flap is turned in over the resected surface of the phalanx if such tissue is available The toe is then bandaged in neutral position except for a few degrees of plantar flexion Movements are begun on the fifth day, and weight-bearing is allowed after the tenth day

The functional results of this simple operation are excellent Only one failure is noted in the series, 31 operations were followed by symptom-free activity, and all patients were doing normal work without difficulty The one failure resulted from the formation of a long, lateral horn of bone from the remaining portion of the phalanx, which gave painful contact with the metatarsal head Reoperation was successful

It is important to remove from one-half to two-thirds of the proximal portion of the phalanx, otherwise insufficient joint space will remain, and painful contact may result If too great a portion is removed, the toe may become flail and unstable There is a tendency to dorsiflexion following the operation, and this can be overcome by bandaging the toe in slight flexion at the time of operation

NEWTON C MEAD, M D

The Late Results of Operative Treatment of Recent Dislocation of the Patella M FELLÄN *Acta orthop scand*, 1948, 18 157

The causes of dislocation of the patella may be congenital, as in defects of the femoral condyles or in the quadriceps muscle, the vastus medialis being deficient and the vastus lateralis being relatively too strong The tibial tuberosity is sometimes placed too far laterally which gives the mechanical effect of a valgus deformity of the knee and tends to pull the patella laterally Defects in the femoral condyles which lead to patellar dislocation are (1) a lack of the groove between the condyles and a corresponding failure of the patella to develop a sagittal crest and two articular facets to contact the two condyles, (2) the lateral condyle may be poorly developed Operation, if necessary, should be done before too many dislocations have occurred, since many recurrences inevitably lead to permanent degenerative changes in the patella as well as in the rest of the joint

More than 70 different operations have been devised for this dislocation Obviously, none of these is entirely satisfactory The patients in the series here presented were operated upon by the method of Krogus, in which the lateral tissues are slackened and the median parapatellar tissues are tightened without entering the joint In nearly all cases this was accompanied by a transposition of the tibial tuberosity and occasionally by some other procedure such as osteotomy to correct the valgus deformity In 13 cases in this series the underlying disease was dysplasia of the femoropatellar joint, in 1 case it was persistent genu valgum, in 11 cases the cause was purely traumatic, and in 6 cases the cause was uncertain

There was a recurrence in 2 cases of bilateral, and in 4 cases of unilateral dislocation All cases in which there had been no recurrence showed excellent results The author believes that the prognosis is worst in patients with dislocations beginning early in childhood and in whom many dislocations have occurred The poorest results from surgery were

FRACTURES AND DISLOCATIONS

The Importance of Intramedullary Nailing for the Treatment of Pseudarthrosis (Ueber die Bedeutung des Marknagels fuer die Behandlung von Pseudarthrosen) H NUSSELT *Chirurg*, 1949, 20 211

Since fractures of the long bones have been treated at an increasing rate by traction, the incidence of pseudarthrosis due to overextension has definitely grown Treatment of pseudarthrosis due to bone defect by grafting only is often doomed to failure, especially in lesions close to a joint Intramedullary nailing permits exact fixation and ideal support of the graft with a minimum of wiring, only one

observed in "permanent" dislocations, relapses occurred in 4 of 8 cases

Follow-up studies were made on 14 cases of recurrent dislocation of the patella in patients who were not operated upon. Osteoarthritis of a more or less severe degree developed in 12 of these, the 2 remaining patients obtained complete recovery.

Three patients with permanent dislocations had surprisingly good function despite their osteoarthritis.

The author believes that recurrent patellar dislocations should be operated upon as early as possible, and that permanent dislocations which would show poor results following operation, and which manifest no serious symptoms if left alone, should not be operated upon.

The Krogus operation combined (in suitable cases) with transposition of the tibial tuberosity gives good results. The prognosis is favorable when the outline of the femoropatellar joint is normal and no serious changes exist in the cartilage. The more marked the dysplasia of the femoropatellar joint, the greater is the risk of recurrence. **NEWTON C. MEAD, M.D.**

A Comparative Study of Methods of Treatment of Diaphyseal Fractures of the Leg **GUSTAF-ADOLF LANDOFF** *Acta orthop scand*, 1948, 18: 37

It has appeared in the recent literature that treatment of shaft fractures by traction has given results less satisfactory than immobilization in plaster or by internal fixation. Good control studies of comparison of the various methods have been rare.

It is difficult to know the exact time at which a fracture may be considered healed. The author uses the formation of the callus bridge, as seen in the roentgenogram, as his index.

The present study deals with 301 cases of leg fracture in which adequate records and follow-up data were available. One hundred and thirty of the patients were under 20 years of age. Healing was faster in this group of patients than in those who were over 20 years of age. The adult group showed little difference in healing time regardless of age.

The site of fracture was unimportant. Fractures of the lower third of the leg healed just about as well as those of the middle third. The type of fracture, whether spiral, oblique, or transverse, had little effect on the healing time. With the use of traction on 5 comminuted fractures of the tibia the healing time appeared to be prolonged (24-7 weeks), but the series was small and the many factors involved render this figure valueless.

A comparison of the traction-treated fractures (oblique) with those treated by manipulative reduction and casts shows that those treated by traction took 3-7 weeks longer to heal. The factors causing this delay are not all understood, but even a small displacement of fragments was shown to have an unfavorable effect on callus formation. Any form of movement in the callus mass disturbs the formation and deposition of calcium crystals. It is well known that distraction has an unfavorable effect on

bone healing. Frequent roentgenograms (as required in fractures treated by traction) have a definitely inhibitory effect on the regenerative capacity of osteogenic tissue.

Traction over a long period of time seemed to be associated with delayed union, but these figures were unsuitable for statistical analysis.

Patients treated by primary open reduction and internal fixation (17) constituted a rather small group. Healing callus was observed in 12-4 weeks. Delayed open operation was usually required because of overtraction, or malposition uncontrolled by traction, and these patients were improved following operation.

The author concludes that weight traction is less suitable than plaster for closed shaft fractures of the leg. As a means of correction, weight traction may be excellent, but it should be used with discretion and indications for its use should be within narrow limits, the method being resorted to only in special cases, i.e., in cases in which there is definite shortening or in which repeated manual reposition plus fixation in plaster has failed. In obviously troublesome cases, open reduction sometimes combined with osteosynthesis ought to be considered at the very beginning of treatment. Open reduction does not delay union. **NEWTON C. MEAD, M.D.**

Isolated Fracture of the Tarsal Scaphoid. End Result of Scaphoidectomy (Sulla frattura isolata dello scafoide del tarso. Risultato a distanza scaphoidectomia) **M. SOLERO** *Chir. org. movim.*, 1949, 33: 45

The author reports a single case of comminuted fracture of the tarsal scaphoid treated by scaphoidectomy. A follow-up study 5 years later revealed a mild varus deviation of the forefoot, but with a good plantar arch and an excellent functional result.

The patient was a man 35 years of age who injured his foot in a bicycle accident. Shortly thereafter, because of severe pain on weight bearing, he was admitted to the Ospedale Maggiore of Trieste.

The author gives a good résumé of the subject in the literature and describes the various methods of treatment. All authors report most favorable reports from their particular method of treatment whether it be arthrodesis, midtarsal resection, simple immobilization, or removal of the entire fractured bone.

Five years later, plantar footprints of the patient whose case was reported revealed no difference in the two feet. **CARLO SCUDERI, M.D.**

ORTHOPEDICS IN GENERAL

Fundamental Concepts in the Treatment of Completely Arrested Volkman Contracture (Conceptos fundamentales en el tratamiento del Volkman completamente constituido) **PEDRO V. PEDEMONTÉ** *Arch. urug. med.*, 1948, 33: 123

Volkman's contracture is a lesion affecting the muscles and tendons and resulting in a disproportion

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

Fig 1 (Hellstadius)

Fig 2

Fig 3

between the bony and soft parts. This is illustrated by the act of hyperextending the wrist at which time the typical claw hand is created.

To correct this deformity Pedemonte performs an arthrodesis on the radius and ulna. The extent of the fusion is precalculated to permit extension of the fingers during extension of the wrist. This procedure eliminates the need for tendoplasty which in some instances assumes formidable proportions.

The author is emphatic in restricting this procedure to the arrested Volkmann's contracture. In cases in which contraction is still progressing he advises physical therapeutic and orthopedic measures. It is considered a mistake to employ arthrodesis until the disease has been completely arrested. This is determined more from clinical studies than from the time element.

STEPHEN A. ZIEMAN, M.D.

A Contribution to the Question of the Origin of Anterior Paradiscal Defects and So-Called Persisting Apophyses in the Vertebral Bodies

ARVID HELLSTADIUS *Acta orthop Scand*, 1949 18 377

Previously the author has reported cases of dorsal insufficiency in which roentgenography showed a special characteristic lesion of the vertebral body, viz, a defect in the anterior part, adjacent to the intervertebral disc. He believes that this defect represents an impaction of the disc tissue into the vertebral body similar to the impaction of the nucleus pulposus into the central and posterior parts

which is commonly referred to as a Schmorl's node. The common mechanism of origin of the defects is impaction of disc tissue subsequent to a single or repeated trauma. About half of the cases occur in the teen-age group and are brought to light because of the symptoms. A table representing 17 defects in 16 individuals is presented. In 4 instances the lower vertebral border was affected. The author describes three conditions associated with these anterior paradiscal defects.

The first condition, and most common, is a discrepancy in the anteroposterior diameter of the adjacent vertebrae. The superior one is usually narrower than the one below, and the anterior-inferior angle of the upper vertebra impinges into the vertebra below (Fig 1).

Another associated condition is a rounding of the anterior-inferior angle of the vertebra which allows it to impress into the adjacent vertebral body (Fig 2).

A third, less common and less certain mechanism is that of persisting anterior vertebral apophysis. It is thought that the nonunion of the apophysis may be due to impression of the adjacent vertebral angle (Fig 3).

The author has looked for the condition in spondylolisthesis. Despite the unevenness of the adjacent vertebral angles he has not seen the paradiscal defects. He attributes this to the degeneration of the disc and loss of elasticity in this condition.

KENATH H. SPONSEL, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Observations on Raynaud's Disease, a Report of 35 Cases (Réflexions sur la maladie de Raynaud—à propos de 35 observations) P WERTHEIMER and R. GUILLET *Lyon chir*, 1949, 44 145

The authors report the results of surgical treatment of 35 patients with Raynaud's disease. There were 20 women and 15 men. Their ages at the time of surgical treatment varied between 23 and 70 years, and the duration of their symptoms before treatment averaged 10 years. The authors emphasize that the disease may have its onset at any age in life except infancy.

A total of 70 operations were done on 35 patients without a fatality. These included 15 periarterial sympathectomies, 35 stellate ganglionectomies, 1 cervical ramisection, 4 resections of the superior portion of the sympathetic chain below the stellate ganglion, 3 thoracic sympathectomies, 4 lumbar sympathectomies, 1 splanchnicectomy, 3 parathyroidectomies, 2 thymectomies, and 1 adrenalectomy.

All of the patients who underwent periarterial sympathectomy retained their sensitivity to cold. In 5 (33%) the progress of the disease was checked. Although the operation has the advantage of a simple, nontraumatizing procedure, the authors do not recommend it in the treatment of Raynaud's disease.

Three patients who had unilateral stellate ganglionectomy had obtained satisfactory results when observed 6, 4, and 2 years, respectively, after surgery.

Among the patients who underwent bilateral stellate ganglionectomy there were 10 who had single ulcerating lesions of the upper extremity. Three of these patients were cured, and in the other 7 patients the trophic lesions healed but the patients remained sensitive to cold. In 1 patient following stellate ganglionectomy, nerve blocks of the upper thoracic sympathetic chain produced appreciable vasodilatation in the upper extremity. This indicates that removal of the stellate ganglion produces only partial sympathetic denervation of the upper extremity.

Five patients with multiple severe ulcerations of the upper extremity underwent bilateral stellate ganglionectomy. The beneficial results which occurred were only temporary in the 3 patients who were adequately followed.

Three of 4 patients who underwent resection of the superior portion of the thoracic sympathetic chain below the stellate ganglion obtained good results, as did the patient who underwent unilateral cervical ramisection.

Operations on the endocrine glands did not alter the course of the disease appreciably in any patient.

The authors conclude that periarterial sympathectomy is not as effective as stellate ganglionectomy or

resection of the upper portion of the thoracic sympathetic chain in the treatment of patients with Raynaud's disease. The most effective procedure of any which they investigated was resection of the upper portion of the thoracic sympathetic chain, with or without stellate ganglionectomy.

FREDERICK W PRESTON, M D

Arteriotomy for Arteritis Obliterans of the Lower Extremities (L'endartériectomie pour artérite oblitérante des membres inférieurs) LOUIS BAZI *J internal chir*, 1949, 9 95

The author presents an operation for the relief of acute or chronic arterial occlusion. The procedure is applicable to thromboses of the femoral, popliteal, tibial, and iliac arteries, and the lower part of the abdominal aorta.

The extent of the occlusion is first accurately determined by an arteriogram made on the operating table. The artery is then incised along the entire length of the occluded portion. The thrombus and adjacent necrotic portion of the arterial wall are then removed, and the artery is repaired with carefully placed sutures of fine silk. The operation could well be called an intra-arterial sequestrectomy. During the first 48 postoperative hours heparin is given intravenously and the blood clotting time is measured every 3 hours. The interior of the vessel becomes lined with a unicellular layer of leucocytes and later endothelium grows in from either end of the reconstructed portion. Lumbar sympathectomy is not done in conjunction with this operation.

The operative procedure requires exact hemostasis and careful attention to other details. Usually the procedure takes from 2 to 6 hours. The author attributes the success of the operation to the fact that a partially necrotic artery is replaced by a totally viable one.

Two important causes for operative failure are (1) leakage at the suture line which results in an extra-arterial clot that may form an intraluminal extension and cause the artery to become reoccluded, and (2) a reconstructed arterial wall which is too thin and therefore may allow aneurysmal dilatation which in turn may lead to further arterial occlusion or to rupture of the arterial wall.

FREDERICK W PRESTON, M D

Obstruction of the Superior Vena Cava. A Review of the Literature and a Report of 2 Personal Cases FLOYD T MCINTIRE and EDWIN M SYKES, JR *Ann Int M*, 1949, 30 925

The literature for the period from 1904 to 1946 was reviewed by the authors and 250 authentic cases of obstruction of the superior vena cava were found, 145 of these were verified at autopsy or surgery. Bibliographic data are tabulated according to etiology. Comparisons are made with Fischer's

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

collection of 252 cases prior to 1904, and composite figures are presented of the total incidence of important etiological factors in 502 cases from the world's literature up to January, 1946, inclusive. The first authentic case report was by William Hunter in 1757.

In regard to the incidence of the syndrome under consideration, varying opinions are expressed in the literature. The authors are in accord with the opinion that varying degrees of superior vena caval obstruction occur not uncommonly, and much more frequently than is generally suspected. Common lesions such as aortic aneurysms, mediastinal malignancies, and chronic inflammatory diseases are responsible for the caval obstruction in a substantial majority of reported cases. The frequency of space-occupying lesions of the superior vena cava, the anatomical relations of this vessel, and the increased compressibility of this vessel, and the increasing number of case reports in the literature constitute very suggestive evidence that the syndrome is not uncommon.

The applied anatomy of superior vena caval obstruction is presented by the authors and particular emphasis is given to collateral circulatory routes and the mediastinal lymphatic system. The importance of the relationship of certain mediastinal lymph nodes to the superior vena cava has not been sufficiently stressed in medical literature dealing with obstruction of this vessel. Two important chains of lymph nodes are intimately associated with the vessel. The right anterior mediastinal chain, the right laterotracheal chain, and the right innominate vein, and consists of two to five nodes, the latter lies on the posterior aspect of the same vein and consists of three to six nodes, the largest and most inferior of which lies on the superior surface of the arch of the vena azygos. The right bronchial nodes and some of the nodes of the tracheal bifurcation are in fairly close association with the lower portion of the vena cava, both of these groups of nodes in turn drain into the right laterotracheal chain. Most of the structures of the right thoracic cavity, mediastinum, and part of the structures of the left thoracic cavity drain into either or both the right anterior mediastinal and the right laterotracheal chains. The frequency of neoplastic and inflammatory disease in this part of the body serves as a constant threat to these lymph nodes, with possible obstruction, partial or complete, of the superior vena cava from extrinsic pressure or invasion.

Trends in etiology in the past four decades are discussed. In the series of 250 cases studied by the authors, the sex is given in 166 of these. Seventy-nine and five-tenths per cent of the patients were males and 20.5 per cent were females. The sex incidence is explained on the basis of preponderance of aneurysms, bronchogenic carcinoma, and malignant lymphoma in the male. The highest incidence is from 30 to 60 years of age, probably corresponding

to the age incidence of the common etiological factors, more particularly neoplasms and late syphilis, including aortic aneurysms. Malignant primary thoracic tumors, aneurysms, and chronic fibrous mediastinitis are responsible for the obstruction in from 75 to 80 per cent of the cases. Primary thoracic tumors, benign and malignant, account for 35.9 per cent of the cases. Approximately 93 per cent of these tumors are cancerous. Syphilis accounts for 34.8 per cent of the cases in the authors' series. Approximately 69 per cent of these are aortic aneurysms.

Nineteen cases of localized phlebitis with thrombus formation have been reported since 1904, of these, 16 were verified by autopsies. With regard to etiology, in 11 cases the condition was of unknown cause, in 3 the phlebitis was associated with cardiac disease, in 3 others it was caused by mediastinitis, in 1 case it was associated with silicosis, and in 1 the condition was classified as tuberculous endophlebitis.

Detailed consideration is given to chronic fibrous mediastinitis of idiopathic, or nonspecific, origin. Etiologic factors are indefinite, but it seems likely that a mild inflammation of the mediastinum in an individual with tendency to excessive cicatrization may slowly progress to form the typical dense mass of fibrous tissue. For the development of the scar factor there must be some antecedent etiological factor such as upper respiratory infection, influenza, bronchopneumonia, tularemia, trauma, rheumatic fever, plus occasionally a tendency toward the development of excessive amounts of cicatricial tissue.

The symptomatology and clinical findings of the syndrome under consideration, except for the primary pathology involved, is secondary to obstruction of circulation in the superior vena cava. This obstruction causes increased venous pressure in that part of the body which normally has its venous return to the superior vena cava, and collateral diversion of the blood stream. As a result of this obstruction and the coincidental change in venous pressure, dilated veins are often visible in the upper half of the body, and edema in the upper extremities, head, and neck is frequently noted. Often cyanosis and dyspnea are present. Headache and chest pain are commonly troublesome. Other signs and symptoms such as hoarseness, dysphagia, drowsiness, and occasionally convulsions are sometimes associated with this syndrome. These clinical findings in the presence of elevated venous pressure in the upper extremities, and normal venous pressure in the lower extremities are sufficient to make a diagnosis of superior vena caval syndrome.

The authors observe that the treatment of this condition is largely a matter of treating the primary disease. Symptomatic relief may be afforded by repeated phlebotomies, surgical intervention in selected cases may be justified in an attempt to relieve the obstruction, if it is due to external pressure. Two cases of chronic fibrous mediastinitis are presented by the authors, one verified by surgery,

INTERNATIONAL ABSTRACTS OF SURGERY

both apparently a result of previous acute infection of the respiratory tract. In the first case the point of obstruction of the superior vena cava was demonstrated, by angiocardiograms, to be below the azygos opening, proving the lesion in this location to be compatible with life. The azygos is shown to be the important collateral system in caval obstructions below the azygos opening.

HERBERT F. THURSTON, M.D.

MISCELLANEOUS

Amputation for Gangrene Due to Occlusive Arterial Disease SAMUEL PERLOW and HAROLD A. ROTH
Surgery, 1949, 25: 547

The published statistics of mortality following amputation for gangrene of an extremity in the older age group vary from 4.7 to 39.1 per cent and higher during which series the authors' operative mortality rate was reduced from 25 per cent in 1936 and 1938, to 11.7 per cent in 1945 and 1947. The means by which this reduction was accomplished are presented in some detail.

There were 124 amputations above the knee, 19 below the knee, 6 through the foot, and 16 of the toes. Although all of the deaths followed amputation above the knee, it is believed they were due to the poor condition of the patients rather than to the level of the amputation. Of 22 patients undergoing minor amputations, 10 (45.5%) later required major reamputations. There were 7 of 14 (50%) diabetic patients who had reamputations, 2 of 3 patients (66%) with senile arteriosclerosis who had reamputations, and of 5 patients with thromboangitis obliterans, 1 (20%) was subjected to a second amputation. In the patients with diabetic and senile arteriosclerosis, minor amputations were successful

only in the presence of a pulsating vessel at the ankle or after preliminary sympathectomy. It has been concluded by the authors that all minor amputations should be preceded by a sympathetic ganglionectomy.

Ten of the 28 hospital deaths were due to cardiovascular accidents: cerebral hemorrhage, coronary occlusion, and so forth. Fourteen deaths were due to pneumonia, sepsis, and decubitus (before the era of penicillin). The average age of the patients at the time of death was 66.5 years.

Preliminary ligation of the femoral vein on the side of the amputation was carried out in 34 of these cases as a prophylaxis against pulmonary embolism. One of the patients died due to embolism originating in the opposite leg.

One hundred and seventeen amputations were performed under general anesthesia, 23 under spinal anesthesia, 22 under refrigeration, and 3 under nerve block. Refrigeration was used for the acutely ill or debilitated patients and poor risk diabetics. Moreover, it was found possible, by means of refrigeration and tourniquet, to effect a physiologic amputation for several days before actual removal of the limb, which enabled the surgeons to carry out adequate preoperative measures. Oxygen therapy, blood transfusion, and antibiotics were given to the poor risk patients preoperatively, and oscilometric readings were made to determine the level of amputation.

The authors express a marked preference for amputation below the knee and frequently perform a preliminary lumbar sympathectomy so as to improve the popliteal and femoral pulsations and thereby permit the lower amputation.

All major amputations are planned for a side-bearing stump. The technique for supracondylar and below the knee amputations is given in detail.

JANE C. MACMILLAN, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE, POSTOPERATIVE TREATMENT

Major Surgical Operations in the Presence of Bundle Branch Block PAUL H. PFEIFFER and JOHN S. LA DUE *Am J M Sc*, 1949, 217 369

A statistical study was made of 59 patients with bundle branch block who were subjected to radical surgery for the ablation of cancer. The bundle branch block of the elderly patient was usually associated with arteriosclerotic heart disease.

In this group there were 30 patients with right bundle branch block and 29 patients with left bundle branch block. In 49 per cent of the patients the diastolic pressure was 90 mm or higher. X-ray evidence of cardiac hypertrophy was demonstrated in 26 per cent of the patients. The majority of the operative procedures lasted between 2 and 4 hours. The immediate postoperative mortality was 10 per cent. In 5 patients there were signs of progression of the disease processes in the heart after operation. Practically all of the patients who showed the S-wave type of bundle branch block did not seem to be related to the operative or postoperative course.

Bundle branch block is not in itself a contraindication to major surgery, especially with good medical supervision. Evaluation of the patient's status is best made by study of the medical history, cardiac classification, and physical findings rather than the interpretation of the electrocardiogram.

BENJAMIN G. P. SHAFIROFF, M.D.

Experimental Study of Fatal Pulmonary Embolism
(Contributo sperimentale allo studio dell'embolia polmonare mortale) F. URSO and G. TROIA *Arch ital chir*, 1949, 71 127

The authors produced pulmonary embolism in dogs by injecting 15 cgm of marble dust per kilogram of body weight. The particles were homogeneous and measured 150 microns, and they were injected in 10 c.c. of physiological solution. Death resulted in 51 per cent of the dogs in from 2 to 5 minutes without any embolus in the pulmonary artery. The particles were found in the peripheral branches by histologic study.

The dogs which did not die immediately were sacrificed and presented the same anatomicohistological picture.

Most likely, death was due to massive reflexes which began in the intima of the arteries and produced first paralysis of the respiratory center and then of the cardiac center (pulmonary shock).

That 49 per cent of the dogs were able to survive is taken to mean that there is a great variation in the intensity of these reflexes in different dogs.

In order to produce massive embolus with obstruction of the pulmonary artery it was necessary to in-

ject 6 gm of marble dust very rapidly into the external jugular vein.

The authors state that the marble dust is not similar to agents causing embolism in human beings since it is harder and less elastic than the usual agents. They believe that it is more irritating. If emboli that were more like those causing embolism in human beings were used, the death rate from peripheral emboli would be much lower.

These findings are in accordance with data from human pathological anatomy which showed that 70 per cent of the deaths due to pulmonary embolism are caused by mechanical obstruction of the pulmonary artery by massive embolism. The remaining 30 per cent are caused by small peripheral emboli.

ANTISEPTIC SURGERY, TREATMENT OF WOUNDS AND INFECTIONS

Studies on Burns. The Effect of Heparin on the Circulating Blood Plasma and Proteins in Experimental Burns E. MEREDITH ALRICH *Surgery*, 1949, 25 676

Previous studies showed that when an animal is heparinized following experimental burns less swelling occurs in the burned area. Furthermore, it was demonstrated that lymph can be collected from a burned area by cannulization of a lymph vessel for a longer period in an animal which has received heparin than in animals not so treated. Because of these observations it was postulated that heparin, by preventing the coagulation of plasma lost into the tissues and thereby allowing it to return to the general circulation by way of the lymphatics, might decrease the amount of edema fluid in the traumatized area.

To study the effects of heparinization after experimental burns on the plasma volume and proteins, dogs were given a standard burn by immersing their hindquarters in water at 75° C for 5 seconds. Seventeen animals then received 10 mgm of heparin intravenously and 10 mgm subcutaneously each hour for 8 hours. A control group of 6 animals received no heparin. Five of the animals in the experimental group died within 30 hours after burning, presumably from the effects of overheparinization. Plasma volume, protein, and hematocrit determinations were made on the animals at standard intervals throughout the experiment. The results indicated a greater loss in plasma volume and plasma protein after burning as compared with the nonheparinized animals. The reverse was found to be true in the period from 12 to 30 hours after burning. The early greater loss of plasma (both volume and protein) and its more effective recovery are explained by the absence of coagulation of the exudate in the tissues and in the lymphatics following heparinization. The

authors state that the high mortality in the heparinized group precludes the use of heparin at the present time in the treatment of clinical burns

C FREDERICK KITTLE, M D

Some Observations on the Treatment of the Dorsal Burn on the Hand FENTON BRAITHWAITE and J WATSON *Brit J Plast Surg*, 1949, 2 21

Severe burns of the dorsal surface of the hand, if improperly treated, may cause crippling deformities. The initially deforming posture, assumed by the patient to achieve maximum relief from pain, may become a fixed one as the persistence of the burn slough gives rise to infection, suppuration, edema, and fibrosis. The individual changes in each of the tissues and structures of the back of the hand are listed and discussed concisely by the authors.

The skin contracts as it heals by scarring. This contracture draws the metacarpals together, ultimately displacing the heads of those for the index, ring, and little fingers dorsalward and thus producing a convex palmar surface of the hand. The proximal displacement draws the skin of the dorsum of the proximal phalanx onto the hand and thus hyperextends this phalanx. Contraction and adhesions of the fasciae over and under the extensor tendons obliterate the superficial and deep dorsal spaces of Kanavel and render the tendon complex immobile. The hyperextension deformity shifts the axis of the interosseous tendons so that they increase the deformity instead of initiating flexion of the proximal phalanx. The collateral ligaments of the metacarpophalangeal joints contract and thus block flexion at these joints. The synovium of the joint itself contracts and further aggravates the hyperextension deformity. If the burn causes a loss of the insertion of the extensor tendon into the base of the middle phalanx the delicate balance of flexors and extensors may be lost. The extensors can extend the proximal phalanx and the flexors can flex the middle phalanx, but co-ordinated movement is impossible.

The treatment of an established hyperextension deformity is long and tedious and may be only partially successful. Arthrodesis of the proximal interphalangeal joints in a position of semiflexion is helpful. Prolonged physiotherapy and re-education are essential. If the period of immobility of the hand is very long the motor cortex seems to lose its concept of a patterned integrated movement. The best treatment is prophylactic.

Early cure should consist of complete excision of the burn slough and any granulation tissue present, and the application of a skin graft to cover the whole defect. This eliminates the need for prolonged splinting, although the proximal interphalangeal joints may require individual splinting, which will permit movement at the metacarpophalangeal joints. The best time for the excision of the slough and application of the graft seems to be from 12 to 18 days after the burning. The best base for the graft is the fascia enclosing the tendons.

BENJAMIN L. LOUNSBURY, M D

Recurrent Tetanus (Du tétanos récidivant) RIVER J PICASSOT and J RIVET *Bull Soc Méd Exp Paris* 1949, 65 98

The authors call attention to the fact that in 1946 recurrences of tetanus were observed after intervals of several years without any evidence of reinfection. Three such cases are described.

The symptoms of the recurrent attacks presented no special features. The general symptoms were less marked and rapid generalization was unusual but classic contractures were almost always noted as well as paroxysmal exacerbations suggesting localized tonic-clonic epilepsy. One case illustrated the hepatoglomerulonephritis occasionally observed in tetanus. The course was usually benign, although 1 fatal case was reported (Chavany).

These cases constitute further indication that tetanus does not immunize the organism, and that the effect of antitetanic serotherapy, although powerful, is not lasting. It does not act on the sporular forms which survive in a weakened condition in an apparently cured organism. Some adjuvant cause may serve to activate the spores and thus favor recurrence. It is wise, therefore, to combine serotherapy with active immunization with antitoxin.

The 3 patients observed all recovered promptly following the administration of antitoxin, although in 1 case only after an attack of uremic coma.

EDITH SCHANCH MOORE

Tetanus Treated as a Respiratory Problem AFRON C TURNER and THOMAS C GALLOWAY *Arch Surg*, 1949, 58 478

The recognition of the importance of respiratory obstruction due to tracheal and pharyngeal secretion in certain conditions and the ability to control it have led to a completely changed prognosis in many diseases. This has been true especially in bulbar poliomyelitis. During the year 1947 no patient with anterior poliomyelitis died at the Evanston Hospital, Evanston, Illinois, although there were 60 cases, 7 of which were of the bulbar type. Five of these required tracheotomy. One patient with myasthenia gravis, an accumulation of throat secretions, and impending asphyxia was treated with rapid relief.

Certain other states would seem to have the same common denominator of respiratory obstruction, anoxia, respiratory weakness, and danger of drowning from aspirated secretion. The authors thought that tetanus, with convulsions under control by curare, would present much the same picture and respond to the same measures. When a patient with severe tetanus came under their care they found, in fact, that she did respond so remarkably to the treatment on this basis that they believed it could be applied to most cases of severe tetanus with satisfactory results. The treatment was found to be relatively simple and seemed, in retrospect, to be so logical and dependable that they believe it should be adaptable to most serious infection with tetanus.

Curare has been used in the treatment of tetanus since 1894, as reported by Cullen. Tracheotomy was

SURGICAL TECHNIQUE

advised for grave emergencies by Spaeth Isacson and Swenson used a respirator with apparent benefit but without recovery in 1 case of tetanus Tracheotomy was not done So far it has not been found in the literature that the three measures have been combined in any case The authors believe this may be necessary for the reason to be discussed

The combination of the three measures—curare by continuous intravenous drip, tracheotomy, and use of the respirator—is described in detail in a severe case of tetanus and seems to have these definite advantages

- 1 It changed a hazardous treatment requiring unremitting care to a relatively simple, manageable, and easily standardized procedure
- 2 It allowed the use of curare in a latitude of dosage that is comparatively safe
- 3 It guarded against the dangerous period of anoxia
- 4 It by-passed secretions in the upper respiratory passage and permitted aspiration of secretions in the lower airway, and it avoided atelectasis and secondary pulmonary infections due to obstruction

JOHN E. KIRKPATRICK, M D

Streptomycin in Nontuberculous Infections P H Buxton, R D Simon, and F R Selbie *Lancet*, Lond, 1949, 1 729

Streptomycin was given in 67 cases of infection by organisms insensitive to the sulfonamides and penicillin, but sensitive to streptomycin Of these, 44 were cases of urinary infection, chiefly by *Pseudomonas pyocyanea* and *Bacterium coli*, 14 were cases of wound infection, chiefly by *Staphylococcus pyogenes*, and 9 were miscellaneous infections

A short course of treatment with a high initial dose was considered unlikely to give rise to toxic symptoms, and more likely to be effective in preventing the development of bacterial resistance than a protracted course of treatment with low dosage The patients with wound infections were given 4 grams daily for 2 days, and 2 grams daily for 2 more days In urinary infections, the dosage was 3 grams daily for a 4 day course

In wound infections, the results of streptomycin therapy were promising Provided that the wound was freely drained surgically, rapid improvement was obtained In urinary infections, streptomycin is likely to effect a cure in about a third of the cases, unless there is some mechanical obstruction to drainage which produces an inaccessible nidus of infection

Side reactions were encountered in less than a third of the cases, and in only 3, in which there was a severe vestibular disturbance, were they of any significance

SAMUEL KAHN, M D

A Study of Vehicles and Adjuvants for the Sulfonamides and Penicillin EDWIN J PULASKI *Surgery*, 1949, 25 681

Numerous chemical agents were tested for their activity against gram-negative and gram positive

bacteria, and vehicles were investigated to determine which would hold these bacteriostatic agents in wounds in higher concentrations and over longer periods of time than has been possible An extensive group of compounds were surveyed for bacteriostasis: various acids, salts of acids, alcohols, amides, amines, antibiotics, organic bases, dyes, heavy metal salts, detergents, oxidizing agents, organic mercurials, organic arsenicals, sulfur compounds, phenolic compounds, quinolines, and sulfonamides The effect of these was measured by the zone of inhibition of organisms grown on blood and plain agar The action and efficacy of each of the compounds is discussed Those most bacteriostatic were sodium diacetate, p-chlorophenol, sulfamylon, furacin, and streptothricin The action of these varied, acetate lowering the pH, p-chlorophenol having a cytotoxic effect, streptothricin interfering with cell metabolism and reproduction, while the actions of sulfamylon and furacin were not clearly understood

Topical antiseptics are necessary when the unlikelihood of securing adequate concentration by parenteral administration exists Various bases were tested for use as a vehicle and of these, one consisting of white petroleum jelly (10.0 per cent), lecithin (0.2 per cent), carbowax 4000 (10.0 per cent), methocel 15 CP (2.5 per cent), (22.5 per cent), and propylene glycol was found most satisfactory

C FREDERICK KITTLE, M D

ANESTHESIA

The Pharmacologic Actions of Procaine Given Intravenously as an Analgesic Agent ROBERT M ISENBARGER *Anesthesiology*, 1949, 10 343

This article represents a review of the systemic effects of procaine given intravenously Procaine has a special affinity for the sensory components of the nerve fibers because they are smaller (thereby exposing a greater surface area per unit of volume), and because they have a thinner myelin sheath Thus, the differential penetration of procaine occurs with complete blockage of sensation before the transmission of motor impulses is abolished

Used intravenously, this drug produces moderate analgesia, relief of pruritus, and an increased peripheral circulation in a variety of clinical conditions The action appears to be localized to the nerve and blood supply of the affected parts There is some evidence that the metabolites, para-aminobenzoic acid and diethylaminoethanol, retain some of the activity of the injected procaine Toxic reactions depend on the total dose administered, the speed of injection, and the concentration of the solution used When procaine is infused simultaneously with the intravenous administration of pentothal and the administration of curare in the dog, the analgesic, hypnotic, and relaxing action of pentothal and curare seem to be reduced The author has been unable to demonstrate analgesia in dogs from the intravenous administration of procaine in maximum tolerated doses

MARY KARP, M D

INTERNATIONAL ABSTRACTS OF SURGERY

Intravenous Procaine Therapy W J WATT *New Zealand M J*, 1949, 49 127

This article reviews the current literature and records some experiences in the intravenous use of procaine. The method relieves postoperative pain satisfactorily, thus reducing the need for morphine with its attendant respiratory depression and vomiting. As a general anesthetic agent it produces complete freedom from unpleasant aftereffects. It has a particular advantage when used in combination with general anesthetic agents, especially in the prevention of cardiac arrhythmias which occur during cyclopropane anesthesia in thoracic and cardiac surgery. A discussion is given of the pharmacology of the drug and the toxic reactions which might occur with its use.

The following is the author's technique of administration: procaine is made up in from 0.2 to 0.4 per cent concentration with 5 per cent glucose solution. The procaine solution is administered at the rate of 100 drops (6.5 c.c.) per minute until the pain is relieved and then from 15 to 20 drops (from 1 to 1.3 c.c.) per minute to maintain relief from pain.

MARY KARP, M D

Our Experience with Endotracheal Anesthesia with Curare and Artificial Respiration (Unsere Erfahrungen mit der endotrachealen Narkose mit Curare und künstlicher Atmung) KARL MUELLER *Helvet chir acta*, 1948 15 292

For a period of 6 months, the author has used the method of anesthesia described herein in his surgical clinic. He considers it the method of choice for all major intrathoracic and transthoracic operations.

Artificial respiration is assured through airtight intratracheal intubation. No air nor anesthetic is forced into the stomach or esophagus, as occurs in mask anesthesia. The composition of the anesthetic mixture is known and is introduced directly into the lungs. The endotracheal or endobronchial tube permits the accumulated secretions to be sucked out as becomes necessary. The danger of aspiration is reduced to a minimum by means of certain supplementary precautions.

In operations on the lungs the author uses the Trendelenburg position with an intubating intratracheal catheter. The main bronchus on the side of the operation can be blocked off. If it is impossible to use a tampon on account of partial obstruction of a bronchus, the author intubates a main bronchus.

Artificial respiration can be adapted to the surgeon's demands and to the operative condition. The patient must breathe normally because exhaustion of the patient and excessive breathing lead to expiratory flutter and irregular breathing play no part. Air emboli in the lung tissue can be avoided by slow, careful ventilation. For this the author uses oxygen only if one lung or part of a lung is to be removed. Anesthesia in this case is given intra-

venously. By this means the much feared anoxemia is avoided. In such procedures with slow, regular ventilation, whether it be with anesthetic mixture or oxygen alone, one has direct control of the heart action. The pulse rate is dependent upon the respiratory rate.

All striated muscle, except heart muscle, is relaxed by curare. Deep anesthesia is not necessary to block reflexes, e.g., cough reflexes. The patient needs only to be kept in a state of analgesia and amnesia. For this the author uses stichoxydol, a nontoxic, nonexplosive drug, kind to the mucous membrane, and quickly eliminated from the body. The gas is in a concentration of 40 per cent to the body and does not lead to any great amount of anoxemia. With a concentration of 40 per cent nitrogen monoxide and 60 per cent oxygen analgesia is obtained, with a concentration of from 40 to 75 per cent nitrogen monoxide. Unconsciousness is obtained. Deep anesthesia occurs first at between 85 and 90 per cent nitrogen monoxide. With the use of curare, the author seldom uses this concentration. Usually a light anesthesia can be prolonged for several hours without danger of pulmonary or other complications. The duration of the operation can be prolonged for a period of 7 hours. The patient usually wakes up with the tying of the last suture. Vomiting and nausea are absent.

After a preoperative hypodermic injection of scopolamine, atropine, and codeine, adults are intubated under a surface anesthesia of 2 per cent pontocaine through the mouth. Intubation under anesthesia allows better control in placing the endotracheal tube and at the same time assures free breathing. In narconumal anesthesia (or similar barbiturates) spasm of the glottis occurs and this makes intubation impossible. After avertin preparation in children, intubation is carried out under deep ether anesthesia and this anesthetic is continued during the entire operation, abundant oxygen being supplemented. After intubation in adults, the author uses from 5 to 10 c.c. of narconumal during induction and basal anesthesia. In old patients and those in poor general condition, narconumal is withheld and the blood pressure readings are recorded.

In the system of the artificial respiration apparatus, a carbon dioxide absorber is used, it is arranged in a sliding pendulum fashion, the so called to-and-fro method.

By light pressure on the rubber respiratory balloon, the anesthetic mixture is forced into the lungs. On account of the elasticity of the balloon after release of the pressure on it, the unused residual mixture is returned after it has given off its carbon dioxide in the absorber. The used anesthetic in the lungs will then be replaced by a fresh mixture conducted through the apparatus. By means of this apparatus, an accurate regulation of oxygen nitrogen monoxide mixture is assured. This method is very economical. The same mixture can be used in the lungs several times. Furthermore, it retains

SURGICAL TECHNIQUE

its moisture and is warmed by the heat of the absorber through carbon dioxide absorption. In this way another cause for postoperative lung complications is avoided.

After carrying out intubation and suction of any secretions present, a continuous drip is led through a cannula into the long saphenous vein. This consists of physiological salt solution with an addition of from 5 to 10 c.c. of coramine to 1,000 c.c. of the solution. This tends to prevent the blood pressure depressant effect of narconumal and pentothal during induction and basal anesthesia. During the entire period of anesthesia, the fluid concentration of the blood is compensated for and the blood pressure is kept as constant as possible by the use of blood transfusions. During induction with narconumal or pentothal, the patient is given only oxygen and then nitrogen monoxide is slowly added until a light cyanosis develops. Curare is given intravenously through a skin incision. The author prefers intocostin as this drug is the weaker of the two and the danger of overdosage is less. Tubarin is 3 times as strong as intocostin. Ether intensifies the effect of curare. If the patient's respirations cease, the oxygen content of the anesthetic mixture is increased until the patient is in a state of light anesthesia. If necessary the patient is allowed to wake up, when a state of analgesia and amnesia exists.

The author is certain that pupillary reflexes are obtainable during the entire operation. Constant control of the blood pressure and pulse rate are absolutely necessary. The patient's color and appearance are not authentic measures for judging his condition. In spite of a rosy appearance, the patient may be in a state of anoxemia which may prove fatal. Blood pressure and pulse recordings are taken every 5 minutes. If the blood pressure drops and the pulse rate increases or if a hemorrhage occurs during the operation, the oxygen content of the anesthetic mixture is increased or oxygen alone is given. Immediately physiological salt infusion with coramine is given. As indicated, blood transfusions are given if there is considerable blood loss. With the tying of the last suture the patient awakens. Nausea and vomiting have not been observed. Patients seem well, but tired. There is no state of shock. The patients may cough after the endotracheal tube is removed. After intervention in cases of lung abscess or bronchiectasis, complete suction of recovery from the anesthesia, complete suction of the bronchial tree with the aid of a bronchoscope is recommended.

With this form of anesthesia, a 7 hour esophagotomy was performed. Of 45 patients operated upon, 6 were over 50 years of age and 4 were over 60 years of age. The greatest amount of intocostin used in a case in which the operation lasted 5 hours and the weight of the patient was 67 kgm was 28 c.c. Prostigmine was used very rarely as an antidote for curare. No more curare than was necessary was

given. If apnea was desired, then the carbon dioxide content in the blood was lowered by hyperventilation so that the respiratory center was not stimulated. Anesthesia was prolonged by a small amount of pentothal for its immediate and brief acting characteristics. Spontaneous breathing occurs when the absorber is removed.

Tamponade of a main bronchus was carried out 4 times. In 2 patients aspiration was performed during the operation on the lung. In 1 case a large undiagnosed lung abscess emptied itself spontaneously and suddenly, so that the patient died 4 days later from a subsequent bronchopneumonia. Another aspiration was without grave consequences. In all of the other cases the postoperative course was uneventful as far as the anesthetic was concerned.

From his experience in these cases, the author concludes that his method of endotracheal anesthesia with artificial respiration and curare gives good results in chest surgery and the experience gained will serve as a sound basis for further developments.

BLACKWELL MARKHAM M.D.

Anesthesia for Thyroid Surgery

STANLEY ROW-
BOTHAM *Proc R Soc M*, Lond, 1949, 42 115

From the anesthetist's point of view, there are two types of thyroid disturbance in which thyroidectomy is indicated: the toxic and the obstructive. This symposium deals chiefly with the former. It is pointed out that the risks associated with operations on thyrotoxic patients have of late years undergone a change because of the introduction of thiouracil. There is a difference of opinion regarding basal narcosis and the anesthetic agents of choice. It is agreed that endotracheal intubation is preferable, and usually it is done by the blind technique after adequate topical anesthesia of the throat and larynx. Nitrous oxide and oxygen is favored, and Hewer advises infiltration of the neck with a 1 to 500,000 solution of adrenalin in normal saline to provide an ischemic field. The use of curare to inhibit the laryngeal reflex is suggested by Forrester.

In respiratory obstruction, a tube is always necessary and no premedication except atropine is given. The throat and larynx are sprayed with 10 per cent cocaine, and anesthesia is induced by pentothal followed by cyclopropane oxygen. Intubation is performed by direct vision.

MARY FRANCES POE, M.D.

Continuous Peridural and Caudal Analgesia in Obstetrics

JOHN G. P. CLELAND *Current Res Anesth*, 1949, 28 61

The desire to produce continuous obstetrical anesthesia which could be attended by a nurse led Cleland to install two indwelling catheters placed peridurally. The first was inserted into the peridural space at the eleventh to twelfth thoracic level so as to obtain anesthesia sufficient to obtund uterine pain without muscle paralysis. The second was placed in the caudal canal to obtund pain at the

outlet without changing the normal resistance which produces rotation. Small repeated doses (from 8 to 12 c.c.) of intracaine which were injected into the upper catheter controlled the pain of dilatation, the injection of intracaine into the caudal catheter was reserved for the second stage of labor and repair.

The author's discussion of physiology is quite clear. The procedure requires the hand of an expert, but the results justify mastery of the technique.

MARY KARP, M D

SURGICAL INSTRUMENTS AND APPARATUS

The Use of Fluorescein in Estimating the Blood Flow in Pedicled Skin Flaps and Tubes WILFRED HYNES and ALASTAIR G. MACGREGOR *Brit J Plast Surg*, 1949, 2 4

A wheal fluorescence test is described for testing the circulation in tubed skin flaps which are to be moved in stages from one place to another. The test is carried out on the seventh day after each stage of the operation and, if negative, is repeated every 3 days. As soon as it becomes positive it is safe to proceed with the next stage of the operation. By this procedure it is often possible to shorten considerably the intervals between the stages of the operation, and thus to minimize the formation of scar tissue under the flap and to divide pedicles with confidence.

An ultraviolet lamp is used, which is appropriately filtered so that the radiation is in the range 3130Å to 4070Å, with 95 per cent of the radiation concentrated at 3650Å. Since ointments and other materials containing a paraffin base fluoresce readily, a preliminary inspection of the skin tube is made with the ultraviolet lamp. Any areas of fluorescence are cleaned with an ether swab.

A rubber-shod intestinal clamp is placed firmly across the end of the tube which is to be divided. A series of intradermal wheals is raised at intervals of 2 to 4 cm along the length of the skin tube by injecting a 1 to 1,000 solution of histamine phosphate. The most proximal wheal is placed at a point on the pedicle, the circulation of which is being tested; the most distal wheal lies 1 cm from the intestinal clamp. Ten cubic centimeters of 5 per cent solution of fluorescein are injected and the room is darkened. Fluorescence under the ultraviolet light is detected at the proximal wheal, and its subsequent course along the tube is noted.

A positive test consists of fluorescence of all the wheals, although at the proximal end of the tube the wheal is brighter than at the distal clamped end.

In an earlier report, one of the authors (Hynes) had described an atropine absorption test for determining the blood supply of skin flaps and tubes. This test consists of injecting 1/25 to 1/50 gr of atropine (dissolved in 0.2 c.c. of water) into the fat of the flap. The injection is made 1 cm from an intestinal clamp previously applied at one end of the flap. Absorption of the drug into the general circulation, manifested by tachycardia, dryness of the mouth, and paralysis of visual accommodation, gives the measure of the blood supply of the injected area.

Both tests were used in a small series of cases in which skin flaps were moved in stages. From a qualitative point of view both tests seemed equally sensitive, but the authors prefer the atropine test for routine use in view of its greater simplicity. The fluorescein wheal test is reserved for patients who already have a tachycardia, or for those in whom two flaps are to be tested simultaneously.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Hemosiderosis of the Lung Due to Mitral Disease
EUGENE P. PENDERGRASS, EDWIN L. LAME, and
HERMAN OSTRUM *Am J Roentg*, 1949, 61: 443

Hemosiderosis of the lung associated with mitral disease is a rare entity. Most of the cases reported to date have appeared in the European literature. Autopsies have been performed in only 17 cases.

Hemosideric nodules in the lungs are demonstrable in chest roentgenograms. These nodules may primarily suggest the diagnosis of miliary tuberculosis or pneumoconiosis. Hemosiderosis may be exogenous or endogenous. Exogenous hemosiderosis is seen in arc welders who inhale ironladen fumes, in silver finishers working with iron oxide, and in grinders of ferrous metal not exposed to silica. The endogenous hemosiderosis is generally found in those who suffer mitral disease with severe anemias, hemorrhage, hemosideric nodules, etc. Although difficult to differentiate, primary differential diagnosis should be made between miliary tuberculosis and pneumoconiosis.

The author presents 4 autopsied cases, all showing a chronic passive congestion, in 2 cases autopsy revealed a hemosiderosis and in the other 2, a siderofibrosis. Pathologic studies show the nodular aggregates demonstrable with the naked eye and identified as hemosiderous deposits. Iron pigment in these nodules vary in size from 1 to 3 mm in diameter. The size, distribution, and shape of the nodules govern the degree of roentgen visualization. These "focal clumps" of hemosiderin and macrophages, with or without fibrosis which are demonstrable in the cause fine nodulations which are demonstrable in the roentgenograms. These phenomena occur rarely in the presence of a chronic passive congestion in patients dying of rheumatic mitral disease. However, the condition may occur in patients with mitral disease who are living comfortably without clinical evidence of congestion of the lungs. The authors report 2 such cases in the living. One patient was followed for 13 years and the other, for several months.

MAURICE D. SACHS, M.D.

Accuracy of Roentgen Diagnosis of Benign Gastric Ulcer C. A. STEVENSON and C. W. YATES *Radiology*, 1949, 52: 633

Experience has shown that a certain number of gastric lesions diagnosed roentgenologically as benign ulcer prove later to be carcinomatous. The diagnostic error is given in the literature as varying between 5 and 20 per cent.

The authors studied the extensive medical literature dealing with benign gastric ulcer and its relationship to gastric carcinoma, and gathered leading opinions concerning the various factors involved. A brief summary of these opinions is given in the first part of the article.

A series of 117 consecutive cases of gastric ulcers diagnosed roentgenologically by various examiners at the Scott and White Clinic of Temple, Texas, is analyzed. In 6 of these (5.12%) the ulcers were located in the upper third of the stomach, in 55 cases (47%) the ulcers were located in the middle third, and in 56 cases (47.86%) the ulcers were located in the lower third.

An adequate follow-up was possible in 91 cases for periods ranging from 10 months to 20 years. In 6 of these the lesions were found to be malignant at operation performed within from a few days to 6 months after the roentgen diagnosis. In 2 of the 6 cases the roentgen report suggested the possibility of carcinoma because of the large size of the ulcer. These 6 cases represent an error of 5.1 per cent in the series of 117 cases, or a corrected error of 6.6 per cent among the 91 cases in which adequate follow-up was possible.

The authors give short résumés of the 6 cases and use the respective roentgenograms for illustration. Even after reviewing the roentgenograms and fluoroscopic findings, it was impossible to differentiate between the ulcers erroneously diagnosed as benign and the proved benign ulcers.

The conclusion is therefore reached that in a small percentage of cases a differential diagnosis between gastric ulcer and early carcinoma is impossible by roentgenologic examination. It may be wise to operate immediately in cases of all roentgenologically diagnosed benign gastric ulcers in the hope of early removal of the carcinoma in the erroneously diagnosed cases.

T. LEUCUTIA, M.D.

Roentgenologic Studies of the Abdominal Aorta in Individuals over 50 Years of Age, as an Aid to the Differential Diagnosis Between Benign and Malignant Ulceration of the Stomach A. ELKELES *Brit J Radiol*, 1949, 22: 280

The relationship of benign gastric ulcer and carcinoma of the stomach to arteriosclerosis has been investigated by roentgenographic examination of the abdominal aorta in individuals over 50 years of age. The abdominal aorta was chosen as the test area since the stomach derives its vascular supply from the celiac axis and, according to postmortem statistics, this vessel is the earliest and most frequent site of general arteriosclerosis.

Benign gastric ulcers were accompanied by the highest incidence of calcification of the abdominal aorta (70%). Calcification of the abdominal aorta was present in 14 per cent of duodenal ulcers and in 23 per cent of control cases. A surprisingly low incidence of calcification of the abdominal aorta (1%) was found in patients with gastric carcinoma.

These observations confirm previous reports, based upon findings at autopsy, which showed that gastric ulcer is frequently associated with generalized ar-

teriosclerosis and that arteriosclerosis and malignant neoplasms are, to some extent, mutually exclusive. The roentgenographic detection of a calcified aorta may thus be an aid in differentiation between benign and malignant gastric ulcers

ALLAN K. BRINEY, M D

Response of the Gall Bladder to Benassi-Vitale's Water Test in the Course of Cholecystography after Gastric Resection (Il comportamento della colecisti dopo prova idrica di Benassi Vitale durante colecistografia nei resecati gastrici) ROSARIO CORSEI *Radiol med*, Milano, 1949, 35 352

Benassi and Vitale have noticed that after the administration of water there is a slight reduction in size of the shadow cast by the gall bladder in cholecystograms. They concluded that water passing the duodenum slightly stimulates contractions of the gall bladder. Not only does the size of the shadow diminish but its intensity increases in a manner similar to that observed after the administration of fats. Probably the gastroduodenal stimulus created by the ingestion of water has a choleric effect and mobilizes rapidly the contrast medium within the intrahepatic biliary ducts. Concurrently, the tonus of the muscular layer of the gall bladder, the so-called peristole, is augmented.

The author employed the water test in patients who had undergone a gastric resection and found that the results were identical with those obtained in individuals with an intact alimentary canal.

This hepatocholecystic test is particularly valuable when the cholecystography fails to visualize the gall bladder, because a defective hepatic cholerisis can be differentiated from an impairment of the ability of the vesicular mucosa to concentrate bile.

The integrity of the efferent lymph vessels of the gall bladder and the pancreatoduodenal lymph glands, in addition to the regulatory autonomic nerves, plays an important rôle in the terminal phase of the phenomenon. The rapid absorption of the water leads to an increase of the concentration of the bile and thus intensifies the shadow.

The author concludes that the oral administration of 200 c c of water in the course of cholecystographic studies serves as a test of the peristolic reflex of the gall bladder.

JOSEPH K. NARAT, M D

The Roentgenologic Picture of Nonspecific Pyelitis (L'immagine radiologica delle pieliti aspecifiche) PAOLO BIONDETTI *Radiol med*, Milano, 1949, 35 191

The 138 cases here reported were observed in the period from 1936 to 1948, at the Civil Hospital in Venice, Italy. From this material were excluded all cases associated with stone and with tuberculosis. In the few cases in which the outlines of the calyces were vague and foggy in outline so as to suggest tubercular involvement, the urinary search for Koch's bacillus was always negative and the condition was ascribed to congestion and swelling of the mucosal lining of the calyces involved. In 14 per cent of these

cases the descending pyelograms were always normal, in 40 per cent the picture indicated a dilated condition of the structures of the renal pelvis, and in 45 per cent the findings suggested a contracted state of the renal pelvic musculature.

The functional state of the kidney did not seem to have anything to do with the pyelographic findings, the dye appeared at the same time on both sides and the involved kidney did not afford any positive evidence of either oliguria or polyuria. Neither did the phase of the infective process seem to exercise any control on the findings, as the contracted and dilated states of the pelvis were more or less indifferently distributed in the early acute phases and in the late, more chronic, stages. The deciding factor as to whether the pelvis reacted to the infective involvement by hypertonic contraction or by hypotonic dilatation seemed rather to be the severity of the infection itself. The renal pelvis was usually contracted in the absence of fever and dilated when the process was so severe as to show a toxic febrile response. Thus, the dilated picture in the pyelogram was a fairly reliable indication of a severe infection.

On the other hand, the presence of contraction did not necessarily indicate the presence of a mild infectious involvement, in fact, the contracted condition was seen in about 15 per cent of cases in the apparently healthy, contralateral renal pelvis. It was also observed in the chronic conditions of the renal pelvis and in patients in whom the pelvis on both sides seemed to be perfectly normal. A mild residual cystitis seemed to be sufficient to produce the picture of renal pelvic contraction, indeed, disease of the neighboring organs, and even a hypertonic constitution in an otherwise healthy individual seemed sufficient to produce it. Of course, in the constitutionally hypertonic subject the contracted state of the renal pelvic structures tended to be equal on both sides, and the contracted condition tended to be more uniform, that is, there was less preference for the ampulla than for the calyces, or for one or more calyces than for the others in the same kidney. Nevertheless, the inequality of contraction is not a reliable indication of the seat of the pyelitis—whether it is unilateral or bilateral.

Ultimately considered, however, these contracted states are seen most often in combination with pyelitis, and a more severely contracted side does suggest that the process may be limited to that side. When considered with other clinical and laboratory methods of urinary examination the contours of the pyelographic shadow are thus of some value in diagnosis and of much greater value in judging the efficacy of treatment. JOHN W. BRENNAN, M D

On the Roentgen Aspect of Prostatic Atrophy NILS P. G. EDLING *Acta radiol*, Stockh., 1949, 31 145

The author believes that the roentgen findings of widening of the prostatic urethra, and a small or absent shadow of the colliculus is characteristic of prostatic atrophy as seen on the urethrocytogram.

PHYSICO-CHEMICAL METHODS IN SURGERY

In marked cases, the volume of the urinary bladder may be greatly diminished and there is incontinence of both the internal and external sphincters.

In less marked cases there may be only widening of the prostatic urethra above the colliculus, without shrinking of the colliculus, or incontinence.

Five case illustrations are presented
VERN W. RITTER, M.D.

Recent Advances in the Roentgen Diagnosis of Pathologic Conditions of the Spine (Recentes aquisições no diagnóstico radiológico da patologia da coluna vertebral) HENRIQUE BASILIO *Rev. bras. cirurg.*, 1949, 18: 63

The value of the standing position in x-ray studies of the spinal column is discussed by the author. The erect position of the patient offers advantages from the physiologic and technical point of view, especially if one is dealing with scoliosis, spondylolisthesis, or a hernia of an intervertebral disc. The importance of films taken in an oblique direction, particularly in patients with spondylolisthesis, is emphasized by the author. He highly recommends Desèze's new method of myelography, called discoradiculography, in which a new opaque medium (discolipiodol) is employed.

JOSEPH K. NARAT, M.D.

An Arteriographic Demonstration of Collaterals Between Internal and External Carotid Arteries F. MARK *Acta radiol.*, Stockh., 1949, 31: 155

A collateral circulation between the external and internal carotid arteries has long been described by anatomists, but this is believed to be the first time it has been described in the literature dealing with intracranial angiography. A brief and partial review of the anatomical and pathologic literature describing this collateral circulation is presented. The anastomosis between the two is usually by way of the ophthalmic artery, either from the internal maxillary artery to the anterior branch of the middle meningeal artery and thence via the lacrimal artery to the ophthalmic artery, or from the external maxillary artery via the angular and posterior nasal artery to the ophthalmic artery.

Two cases of thrombosis of the internal carotid artery (bilateral in 1 case) are reported. In both patients a collateral circulation between the external and internal carotids by way of the ophthalmic artery was demonstrated by cerebral angiography. Three illustrations are presented, which show an absence of dye in the internal carotid above the thrombosis, and yet in each case the ophthalmic artery is visualized as leading to the carotid siphon and the middle cerebral artery.

The existence of this collateral circulation may be responsible for failures of carotid ligation in cases of arteriovenous aneurysms in the cavernous sinus, and in cases in which ligation of the internal carotid is carried out because of an arterial aneurysm.

JOHN W. HOPE, M.D.

Cavity Form of Pulmonary Neoplasm FRANK ISAAC and RICHARD E. OTTOMAN *Radiology*, 1949, 52: 662

After stressing the importance of early diagnosis, the authors briefly review the literature on the cavity form of bronchogenic carcinoma. Based on autopsy material, its frequency is given as varying between 12 and 50 per cent.

Experience shows that the tumor which is more apt to lead to cavitation is the circumscribed, rounded type rather than the infiltrating, stenosing type. The former usually is located in the periphery of the lung, whereas the latter is encountered in the main bronchus. The cause of the cavitation is sought in the inadequate blood supply to the central or deeper portions of the rapidly growing tumor. It is interesting, however, that the condition occurs almost exclusively in primary carcinomas. Metastatic tumors can grow in the lungs to a very large size without showing signs of breaking down. Thus, it appears that infection also plays an important role. It is the authors' opinion that compression of the smaller bronchi within the tumor takes place first, with bronchiectasia distal to the compression. This leads to accumulation of secretions, infection and, finally, necrosis.

There are no characteristic signs by which cavity pulmonary neoplasm can be recognized clinically.

Roentgenologically, the lesion often resembles infected fluid cyst, pulmonary abscess, or ulcerating tuberculosis. The cavity frequently is eccentric and the contours of the inner wall have an irregular, ragged or "bumpy" appearance, corresponding to the irregular tissue necrosis within the tumor. This is especially well demonstrated by laminagraphy.

The authors report 5 cases and use typical roentgenograms and laminagrams to illustrate the salient points. In 3 of the 5 cases the diagnosis was made on the basis of the "bumpy" character of the cavity wall. The authors emphasize the importance of this sign but do not claim that it is pathognomonic. In the fourth case the diagnosis was quite obvious because of the destruction of the adjacent ribs. In the fifth case the diagnosis was not made during the lifetime of the patient.

T. LEUCUTIA, M.D.

Probable Cyst of the Pericardium Associated with Disturbances of the Cardiac Rhythm (Probabile cisti del pericardio associata a turbe del ritmo cardiaco) ADRIANO ASCARELLI *Radiol. med.*, Milano, 1949, 35: 259

The author reports the case of a woman of 33 who developed attacks of palpitations which occurred especially with changes of position and were more frequent and more severe during menstruation and at times of fatigue and overwork. Roentgen examination of the chest revealed a shadow applied to the right side of the heart and presenting transmitted pulsations; the heart was only slightly displaced to the left and was not enlarged; the shadow was unrelated to the diaphragm but was closely connected with the anterior thoracic wall which, how-

ever, showed no bone lesions. The phenomenon of Jansson was not observed. The diagnosis was probable cyst of the pericardium, on the right side.

Cysts and diverticula of the pericardium are very rare and their course is prolonged and benign, which makes the diagnosis difficult. Jansson has reported a sign which he thinks is pathognomonic: the diverticular mass is vertically elongated by deep inspirations and shortened by expirations, especially when the patient is lying down. However, this is also observed in solid tumors of the mediastinum and the heart. The sign has a positive value, but its absence does not impair the diagnosis.

Although the unification of cysts and diverticula is justified from the clinicoroentgenologic point of view, there are criteria of differentiation from the anatomopathologic point of view: cysts do not communicate with the pericardial cavity and they contain more fluid than diverticula. However, by involution of their pedicle, diverticula may lose any communication with the pericardial cavity, which makes their differentiation from cysts difficult.

Pericardial cysts are subdivided into congenital, dermoid, lymphangiomatous, and inflammatory types. Pericardial diverticula are subdivided into properly called diverticula and hernias of the serosa. It is not always possible to distinguish roentgenologically between congenital and acquired cysts and between diverticula and hernias. Both cysts and diverticula may be single or multiple. Distinction between cysts and diverticula is possible only on anatomic examination, and not always then; therefore, the two disorders are clinically and roentgenologically united under the term of pericardial diverticula.

Subjective symptoms may be absent or consist of slight disturbances in the precordial region, oppression, stitches in the homolateral arm or shoulder, sometimes asthenia, dyspnea, cough, and fever. Objective symptoms consist of hypophonesis, a paracardiac shadow fusing with that of the heart, sometimes external fistula, and increased venous pressure because of an obstacle to the emptying of the caval veins. The clinical course is prolonged, periods of disturbances alternating with periods of well being. The prognosis is good.

Roentgenologically, the diverticula usually appear as opaque formations issuing from the contour of the heart and having an oval, semicircular, or, sometimes, polyhedral or polylobal form. More rarely they look like a pendulous, pyriform sac, with the inferior pole in the erect position. Their volume is very variable and remains constant after the first period of development. They are on the right side in 73 per cent of the cases and in the anterior mediastinum in 93 per cent. Their opacity is usually less intense than that of the heart and is practically homogenous. Pulsations are sometimes absent altogether, sometimes the transmitted pulsations are rhythmic but vary from case to case.

Differential diagnosis must be made from aneurysm of the cardiac wall, tumor of the heart and

pericardium, echinococcus cyst, left and right mega auricle, persistence of the duct of Botallo, intra pericardiac and extrapericardiac aneurysm of the ascending aorta, mediastinal lymphogranuloma and lymphosarcoma, benign tumor of the mediastinum, and dermoid cyst.

In the reported case there were attacks of disturbance of the cardiac rhythm connected with sudden changes in the position of the body; these are consequently paroxysmal and postural arrhythmias. The electrocardiograms allowed the conclusion that the rhythmic center of the heart was constant and that the tachycardial crises were of sinus origin, i.e., a paroxysmal tachycardia of nomotopic site (node of Keith and Flack). As to the short duration of the crises, the sudden changes of position probably produced oscillations in the cyst which sent an impulse to the contiguous cardiac tissues. The venous pressure increased suddenly but temporarily on cessation of the stimulation, hence, the sudden but transitory tachycardia. RICHARD KEMEL, M.D.

Some Observations upon the Radiology of the Small Intestine in Old Age. H. J. JUNGMAHN and L. COSIN. *Brit J Radiol*, 1949, 22: 325.

During routine gastrointestinal examinations for suspected peptic ulcer in old people, the authors noted changes in the roentgen pattern of the small intestine which appeared to be pathologic although there were no referable clinical symptoms. This prompted a systematic study of the small intestine in patients between 70 and 90 years of age.

The usual barium follow-through method, as modified by Ross, Golden and Chamberlin, was adopted. There was no special preparation and the patient's last meal was given 9 to 12 hours before the examination. The barium meal consisted of 4 oz. of pure barium sulfate suspended in from 4 to 5 oz. of normal sterile saline solution, so as to avoid the possibility of allergic reactions. Serial roentgenograms were made after 15 minutes, 45 minutes, 1 hour and 45 minutes, 2 hours and 45 minutes, and 4 hours. A preliminary lateral roentgenogram of the abdomen was taken to ascertain the degree of calcification of the abdominal aorta.

First, 8 normal young adults, 7 women and 1 man, were examined. The findings in this group corresponded very closely to those described by Ross and Golden.

The second group consisted of 18 males between the ages of 70 and 91 years. In these, very great variation from the normal was observed. Whereas the transit time of the barium through the small intestine was unaffected, the most important abnormalities concerned the alteration in intestinal tone. In 11 cases there was a definite increase in the tonus involving either the midregion alone (distal jejunum and proximal ileum), or the midregion and the terminal ileum. The hypertonus appeared 1 to 2 hours after the meal and passed off during the later stages of the examination, but in 3 cases it persisted throughout the examination. Hypotonus was

PHYSICO-CHEMICAL METHODS IN SURGERY

found in 3 cases. Segmentation or scattering was noted in 15 of the 18 cases. Three cases showed a marked hyperspasticity during the whole of the survey. The abdominal aorta was calcified in 14 cases.

The authors state that the roentgen findings observed in the small intestine of old people correspond completely with those Ross Golden described as typical of "nutritional disorders." However, the patients of Golden had symptoms referable to the gastrointestinal tract, whereas in the series examined by the authors there were no symptoms.

The conclusion is reached that these roentgen abnormalities of the small intestine represent manifestations frequently occurring in normal persons of advanced age. The most likely cause is arteriosclerosis of the abdominal vessels leading to anoxia of the nerve cells of Meissner's and Auerbach's plexus. The authors also advance the hypothesis that an indirect effect may occur through impairment of the nervous control of the gastrointestinal tract by the pontine centers in case of cerebral arteriosclerosis, with its resultant intermittent cerebral anoxia.

T LEUCUTIA, M D

Medulloblastoma Nonoperative Management with Roentgen Therapy After Aspiration Biopsy

C B PEIRCE, W V COME, J BOUCHARD, and R C LEWIS *Radiology*, 1949, 52 621

In view of the unsatisfactory results generally obtained in the treatment of medulloblastomas, the authors propose a modification of the management of these cases in an attempt to avoid the trauma incident to more extensive surgical intervention. After a careful clinical and ventriculographic orientation of the suspected tumor site, a twist drill aspiration biopsy is taken. The diagnosis once established, roentgen therapy is started immediately.

The twist-drill aspiration biopsy is a simple and safe procedure. At the Montreal Neurologic Institute it is performed in the dressing room immediately off the ward. The same instruments and equipment are used as for ventriculography. In addition, a No. 15 brain biopsy needle is required (using a No. 30 drill). A twist-drill hole (using a No. 30 drill) is placed halfway between theinion and the mastoid process, just below the bulge in the occipital bone. Biopsy is done only if the intracranial pressure is high. The needle is inserted not to exceed a depth of 7 cm. The entire neurosurgical procedure, including shaving the head, can be done in less than 30 minutes.

The authors performed twist-drill aspiration biopsy in 16 cases of suspected cerebellar tumors, and diagnosed the following lesions: 5 medulloblastomas, 2 glioblastomas, 1 abscess, and 1 generalized encephalopathy. In 3 cases the biopsy remained negative, but on subsequent operations a tumor (1 medulloblastoma, 1 astrocytoma, and 1 glioblastoma) was found.

Upon histologic confirmation of the diagnosis, roentgen therapy is instituted. A tumor dose of not

less than 4,500 roentgens is given to the primary lesion in 4 weeks, usually through 3 portals. During the next 2 weeks the entire spinal axis is also irradiated. However, here a tumor dose of only 1,500 roentgens is administered through long narrow fields. During the first 4 or 5 days 100 roentgens only are given daily, to a single port, in order to avoid too much reaction. The following factors are used: 200 kv, 50 cm TSD, and Thoraeus filter, producing a beam with a high value layer of 2.0 mm of copper.

In the 5 cases of medulloblastoma diagnosed by the twist-drill biopsy procedure, the immediate results obtained from roentgen therapy were very impressive. In fact, it is this observation which prompted the authors to publish the present preliminary report. It is too soon, and the number of cases too small, to permit final conclusions.

T LEUCUTIA, M D

RADIUM

Reactions to X-Ray and Radium Therapy in the Treatment of Cancer of the Uterine Cervix

DANIEL G. MORTON and JOHN A. KERNER *Am J Obst*, 1949, 57 625

Radiation therapy for cervical cancer, when administered according to the usual technique employed at the University of California Hospital, carries with it a distinct morbidity and mortality. Radium alone produced little significant general reaction, but its use sometimes caused the induction or exacerbation of infection which occasionally was serious enough to cause death. Local destruction of tissue, and fistula formation were not of common occurrence when radium alone was used.

Roentgen therapy often caused a general reaction and, in some cases, produced so much prostration and general metabolic disturbance that death followed. Proliferative changes in the normal connective tissue structures were also observed, with consequent reduction in the vascularity of the tissues.

The incidence of complications was definitely greater in cases in which both radium and roentgen therapy were used, and increased as the dose increased.

Although the percentage of survivals of patients so treated has greatly increased, the incidence of reactions to radiation has also increased. Of 621 patients, 19 died as a consequence of irradiation, and 2 other patients probably died of the effects of radiation.

Bowel obstruction (not due to cancer) occurred in 38 patients, 76 developed colitis, proctitis, or rectal bleeding, and urologic complications developed in 48 of these, hip fractures occurred in 5 patients, and fracture of the symphysis in 1 patient, there were 16 fistulas which seemed to be the result of the radiation. Many of the patients who developed complications following radiation therapy were anemic, or had a fever before the institution of therapy.

The presence of these complications suggests the need for further study of this problem. Efforts to

INTERNATIONAL ABSTRACTS OF SURGERY

determine the radiosensitivity of tumors should be continued, since reduced amounts of radiation might lessen the complications.

Other methods deserving of further investigation or trial are the use of antibiotics, the role of palliative surgery in cases of radionecrosis without recurrence, continuous hospitalization during roentgen irradiation, and the determination of isotope curves for the method of treatment in use so that over-irradiation can be avoided on a more precise mathematical plan.

Radium Therapy in Carcinoma of the Female Urethra ROBERT E. FRICKE and JAMES T. McMILLAN. *Radiology*, 1949, 52: 533.

A review of the literature revealed that carcinoma of the female urethra is relatively uncommon. The anatomy and lymphatic drainage of the female urethra are discussed.

Treatment may be divided into four general types: cautery, excision, radium, and roentgen therapy. The smaller the tumor, and the more it is confined to the proximal portion of the urethra, the more applicable are cautery and excision in the treatment.

These methods can be used on the distal part of the urethra only at the cost of permanent incontinence. Radiation therapy may be used in conjunction with cautery and excision, although in the treatment of advanced lesions radiation therapy is usually used alone. Many types of radiation may be used: radon seeds or radium needles may be implanted into the tumor; radium tubes may be placed inside the urethra, or they may be placed inside the vagina either in contact with the anterior vaginal wall or in a vaginal applicator.

Thirty-five cases of carcinoma of the female urethra in which treatment with radium was given at the Mayo Clinic, from 1918 through 1942, form the basis of this article. The method of treatment which gave the best 5 year survival was a combination of excision or cautery with radium therapy. The technique of treatment was described in 2 cases. The average age of the 35 patients at the time the diagnosis was made at the Clinic was 52.4 years. A majority of the lesions were squamous-cell epitheliomas. Fifteen (44.1 per cent) of the 34 traced patients survived 5 years or more after treatment was started.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

The Role of the Nervous System as a Cause of the Immediate General Symptoms Following a Burn (Il ruolo del sistema nervoso nell'insorgenza della sindrome generale immediata dopo scottature)
MARCELLO PEREZ *Polichinico, sez chir*, 1949, 56 1

The author observed the blood pressure, pulse rate, respiratory rate, and general muscular reactions of morphinized dogs under ether anesthesia during immersion of one lower extremity in water at 90°C for 30 minutes. The blood pressure became slightly elevated and the pulse and respiratory rates became markedly elevated. There were muscular reactions and the dogs whined. Multiple nerve block in the groin with 1 per cent procaine, previous to the burning, failed to modify the findings as compared to the controls. Section of the femoral artery and vein like soft tissues except the femoral artery and vein likewise failed to prevent the general symptoms noted in the controls. When, however, the perivascular sympathetic nerves were destroyed with 5 per cent phenol in dogs prepared as in the preceding group, the blood pressure and pulse remained stable. There were no muscular twitchings or whining, and the respiratory rate was elevated slightly.

It was concluded that the immediate general symptoms, following a burn are instigated by afferent nerve stimuli from the burned area and not by any toxin. The persistent moderate elevation of the respiratory rate was explained by a rise in temperature of the blood returned from the immersed limb.

N CHRISTIAN MEYER, M D

The Healing of the Wound as a Biologic Phenomenon SAMUEL C HARVEY *Surgery*, 1949, 25 655

The variables and phases of wound healing are discussed. Wound healing is described as a "reaction to injury" that is such a fundamental biologic phenomenon that neither individual organisms nor the species could continue without its existence. The first phase of wound healing is concerned with the removal or neutralization of nonviable material, while the second has to do with regeneration. Both of these stages are dependent upon the persistence throughout life of primordial or cytoblastic cells of degrees of potentiality which exist in the embryo. These cytoblasts persist to a varying degree and are active throughout life even after growth of the organism has ceased. They serve by multiplication and differentiation to replace cells which have become nonviable or to form additional cells for specific growth in response to additional demand. This course is dependent upon the formation of a suitable "field" of induction.

The reaction to injury, and specifically the healing of the wound is a form of growth that, under normal

and uncomplicated circumstances, is primarily autocatalytic and proceeds at a given velocity. This process takes precedence in the body economy and cannot be materially expedited, however, it can be stopped or delayed by many complicating factors. The function of the surgeon is to establish and maintain the optimum conditions for the healing of the wound by avoiding or controlling the factors that are likely to interfere with this normal biologic process.

In the closed wound, for example, a sutured incision, there is an initial latent or lag period of about 4 days when the tensile strength is no greater than that of the suture material. After this the tensile strength increases rapidly but with a diminishing velocity until it reaches a maximum strength in from 12 to 14 days. These figures were obtained by experimentation on the stomach wall. In the skin, tendon, and bone the secondary phase of increasing strength extends over weeks rather than days.

It is pointed out that rough handling, excessive drying of the tissue, circulatory insufficiency, hematoma, serum accumulation, and unnecessary suture material delay the initial phase of healing. Deficiency of ascorbic acid causes the decrease of tissue collagen and the tensile strength is consequently less. Dietary deficiencies, notably protein, retard wound healing.

C FREDERICK KITTLE, M D

Blastomycoses Special Study of Jorge Lobo's Variety (Blastomicoses Estudio especial da doença de Jorge Lobo) JORGE LOBO *Arq med cir Pernambuco*, 1949, 1 3

Five varieties of blastomycosis are described and are named as follows: Busse-Buschke's, Posadas-Rixford's, Gilchrist's, Lutz-Almeida's, and Jorge Lobo's. The last-mentioned condition, caused by the *Glenospora lobo*, is characterized by keloid-like nodules which are the only representative of the cutaneous lesions. The microorganism responsible for the condition has double contours, a diameter of from 8 to 16μ, and produces colonies in the form of concentric rings. All inoculated animals were found to be refractory.

Several photographs of the patients with these lesions are supplemented by photomicrograms. In 1 case described in detail, sulfadiazine did not produce satisfactory results, which necessitated an extirpation of the lesion.

JOSEPH K. NARAT, M D

Congenital Dermal Sinuses LESTER A MOUNT *J Am M Ass*, 1949, 139 1263

Congenital dermal sinuses are due to embryologic failure of the separation of the epithelial ectoderm from the neuroectoderm, which results in a connection between the skin and the central nervous system. Infections may extend down the tube and invade the meninges or central nervous system.

The author reports 5 cases. Two cases resulted in meningitis and subdural abscess. This has been far the most common result of complications in all previously reported cases. The third case, with a thoracic dermal sinus, resulted in an intramedullary abscess of the spinal cord. After drainage of the abscess the patient made a remarkable recovery.

Intracranial abscesses resulting from dermal sinuses have not been reported previously in the literature. The author, however, presents 2 cases in which the sinus started in the occipital area, extended into the posterior fossa, and ended in a cerebellar abscess. Recovery occurred in all cases after surgery.

JACK I. WOLF, M.D.

Multiple Lipoma-Angiolipomas KRISTIAN KROHN
KLEM *Acta chir scand*, 1949, 97: 527

The author presents a résumé of 3 cases of multiple lipoma-angiolipomas and points out the difficulty with which these lesions are differentiated from other benign tumors even after histologic examinations. In one instance the appearance warranted a provisional diagnosis of glomus tumor, the proper diagnosis not being established with certainty until several biopsies had been procured.

This comparatively rare disease consists of multiple subcutaneous tumors of varying size, often painful and generalized in distribution. There appears to be a familial predisposition, and continued recurrence is rare. Microscopically, these tumors present an extremely varied picture of angiomas, lipomas, and combined forms of both. It is suggested that this condition is a variation of multiple lipoma.

DAVID H. LYNN, M.D.

Malignant Disease in Infancy and Childhood
WILFRID F. GAISFORD *Arch Dis Childh*, Lond., 1949, 24: 1

The great advances in prophylactic pediatrics during recent years has resulted in malignant disease assuming an increased prominence as a cause of

death in children. It now ranks higher than some of the commoner infectious diseases of childhood. Between 0.25 per cent and 0.5 per cent of admissions to a children's hospital may be expected to be malignant tumors, in a cancer hospital, between 1 and 2 per cent of the total number of cases are in children. The five commonest sites are as follows: (1) blood, (2) brain, (3) eye, (4) kidney, and (5) bone.

It is not enough appreciated that a large percentage of malignant tumors occur during the first 5 years of life. The sites of malignant tumors in childhood are different from those in adults. Moreover, many childhood tumors are peculiar to this age period and are not seen in later life. Steiner has emphasized that the histologic findings and the clinical progress may be at variance, childhood tumors often exhibit both a dissociation between a malignant histology and a benign clinical course, and tumors appearing to be malignant clinically may show no histologic evidence of malignancy. A third peculiarity is the tendency to rapid progress and wide metastasis in childhood tumors.

Among autopsies of 3,000 newborn infants, Wells (1940) found 4 undoubted malignant tumors, all neuroblastomas. He collected 66 authentic cases from the literature.

Over half of the cases of Wilms' tumor are characterized by progressive swelling of the abdomen in infancy, with the presence of a mass on palpation. Boys and girls are almost equally affected, as are the two sides. It must be differentiated from suprarenal neuroblastoma which may present a similar mass in the abdomen. Recovery from neuroblastoma, even in patients in whom there had been liberal metastasis, has been reported. Retinal gliomas (retinoblastomas) are probably present at birth, and 75 per cent are unilateral. They are not seen after the age of 5 years. The prognosis is good if the affected eye is enucleated before glaucoma has occurred (Wilms reports 12 recoveries among 14 patients).

- Air**, Infection of, with dust liberated from clothing, 207
- Albumin**, Metabolic studies on protein-depleted patients receiving large part of their nitrogen intake from human serum, administered intravenously, 519
- Allergy**, Conditions of eye due to, keratitis rosacea, 24, conditions of eye due to, migraine, 25
- Amines**, Clinicoexperimental study of action, prolonged for years, of some, on bladder of workmen, 491
- Amputation**, Value of transmetatarsal, in management of gangrene of toes, 93, indications for anesthesia and mode of introduction of anesthetic for, of tongue, 201, wounds of extremities, 397, for gangrene due to occlu-sive arterial disease, 596
- Anastomosis**, Thoracoabdominal approach for portacaval, 46 advantages of end-to-end, with separate sutures in surgery of gastrointestinal tract, 560
- Anemia**, Following resection of intestine, 56, frontiers of Banti's disease, 208, sickle-cell, in adults, roentgeno-graphic findings, 409, roentgenologic changes in sickle-cell, 409, of pregnancy treated with molybdenum iron complex, 479, target and resistant red cells in preg-nancy, posthemorrhagic, and blood of umbilical vein, 483
- Anesthesia**, Certain factors influencing percentage of oxy-gen in mixtures of nitrous oxide and oxygen, 97, local, in ophthalmology, 146, indications for, and mode of introduction for amputation of tongue, 201, for thora-coplasty, use of pentothal-curare mixture supple-mented with nitrous oxide-oxygen, preliminary reports, 201, hypobaric pontocaine spinal, for exploration for extruded nucleus pulposus, 201, spinal epidural block, 202, problem of, in Switzerland, 202, for operations for relief of congenital pulmonary stenosis, 242, considera-tions on subject of, for surgery within thorax, re-ported of 309 cases, 299, intravenous demerol scopola-mine, during labor, 300, study of pentothal sodium, and critical investigations of use of succinate as anti-dote, 301, tachycardia in children during, 301, studies of circulation of patients in, by new method for re-cording arterial pressure and pressure pulse contours, 403, convulsions under, in children, 403, pathologic findings in some deaths during, 403, effect of vasocon-strictors upon duration of spinal, controlled study in man, 404, anatomic reasons for failure of caudal, 404, therapeutic uses of intravenous procaine, 405, for neurosurgical procedures, analysis of 1,000 cases, 405, utility of intravenous procaine in, for cardiac distur-bances, 510, pharmacologic actions of procaine given intravenously for, 599, intravenous procaine therapy, 600, experience with endotracheal, with curare and artificial respiration, 600, for thyroid surgery, 601, continuous pendural and caudal analgesia in obstet-rics, 601
- Aneurysm**, Arteriovenous, of lung cured by resection, 350, aid of arteriograms in diagnosis and treatment of intra-cranial, 410, of aorta after resection for coarctation cured by excision, 546
- Angiocardiography**, Diagnosis of pulmonary stenosis by, 203, measurement of normal great vessels, 410, in differential diagnosis of pulmonary neoplasms, 446, in congenital heart disease of cyanotic type with pul-monary stenosis or atresia, observations on tetralogy of Fallot and pseudotruncus arteriosus, 513, in coarcta-tion of aorta, 513

INTERNATIONAL ABSTRACTS OF SURGERY

- Angiography, Vertebral, 345, percutaneous cerebral, and cerebral abscess, 539
- Ankle, Arthrodesis of, 293, arthrodesis of, in posttraumatic conditions, 389, treatment of malleolar fractures according to Lauge Hansen's method, preliminary results, 392, isolated fracture of tarsal scaphoid, end result of scaphoidectomy, 592
- Anomalies, Rare, of esophagus, 451
- Anthrax, Thirty-six human cases of external type treated successfully with penicillin, 97, antibiotic therapy for cutaneous, report of 5 cases, 299
- Antibiotics, Results of systemic administration of, (bacitracin) in surgical infections, 200, therapy with, for cutaneous anthrax, 5 cases, 299, in treatment of diseases of ear, nose, and throat, 534
- Anura, Wounds of extremities, 397
- Anus, Carcinoma of canal of, 58, procedures used in treatment of complicated fistulas, 169, melanopithelioma of, and rectum, 254
- Aorta, Operation of stenosis of isthmus of, 6 cm in length, 42, surgical treatment and physiopathology of coarctation of, 43, treatment of coarctation of, 239, angiography in coarctation of, 513, operative handling of coarctation of, 546, aneurysm of, after resection for coarctation cured by excision, 546, roentgenologic studies of abdominal, in individuals over 50 years of age as aid to differential diagnosis between benign and malignant ulceration of stomach, 603
- Appendicitis, Chronic, in puerperium, 267, emetin and, 559
- Argentafinoma of gastrointestinal tract, 165
- Arm, Indication for operative treatment of fractures of proximal portion of upper, 390, late paralysis of ulnar nerve and occupational accident, 541
- Arteries, Study of circulation of, at angle of duodenum, jejunum, and first intestinal loop, 55, restoration and preservation of continuity of, following trauma, 198, experimental study on use of dicumarol in suture of, 295, ligation of carotid, for advanced malignant neoplasms of head and neck, 344, injuries of, analysis of immediate and late results of injury of, based on military experience, 393, investigation and treatment of disturbances of, in lower limbs, 393, experimental production of gradual occlusion of large, with polythene and tantalum, 500, syndrome of varices of, 500, arteriectomy for arteritis obliterans of lower extremities, 594, amputation for gangrene due to occlusive disease of, 596, arteriographic demonstration of collaterals between internal and external carotid, 605
- Arteriograms, Aid of, in diagnosis and treatment of intracranial aneurysms, 410
- Arteriography in pathologic stumps, role of arterial circulation in genesis of trophic disturbances, 295
- Arteritis, Adrenalectomy in treatment of, 186, ocular complications of temporal, 534
- Artery, Symptoms of pulse in central retinal, 146, unexplained thrombosis of internal carotid, 199, gangrene of face following occlusion of posterior inferior cerebellar, 227, question of gangrene following popliteal injury, 297, surgical anatomy of inferior mesenteric, and Sudeck's point, 454
- Arthritis, Early diagnosis of acute septic osteomyelitis, periostitis and, its importance in treatment, 407, surgery in treatment of chronic, 496
- Arthrograms, 515
- Arthrodesis of ankle joint, 293
- Ascariasis, Gall bladder disease among Filipinos, with report on, of biliary tract, 561
- Atelectasis, Study of postoperative pulmonary, 504
- Axilla, Adenocarcinoma of lymph nodes of, without demonstrable breast lesion, 233
- BACITRACIN, In ocular infections, 27, results of systemic administration of antibiotic in surgical infections, 200, in surgical wound infections, 510
- Banti's disease, Splenomegaly, splenic arteriovenous anastomosis and, 62, frontiers of, 208
- Bandages, Bacteriological analysis of plaster, 310, sterilization of plaster, 310
- Barge-Bourgain's reaction in genitourinary tuberculosis, 385
- Bile ducts, Postcholecystectomy symptoms due to cystic duct of cystic, 58, traumatic rupture of choledochus associated with acute hemorrhagic pancreatitis and bile peritonitis, 60, choledochus cyst associated with congenital atresia of, 60, injuries to, 172, further experience with injured, 257
- Biliary tract, Postcholecystectomy symptoms due to cystic duct remnant, 58, silent gallstone, 10 to 20 year follow up study of 112 cases, 59, reflux into Wirsung's canal in course of cholangiography, 1, dystonia of Wirsung's canal, 60, postoperative dyskinesia of, due to neuroma of cystic duct, 60, anastomosis of external fistula of, into gastrointestinal tract, 173, technical conditions of manometric and radiologic control in course of interventions on, 173, surgical jaundice, collective review, 209, peritonitis due to, 255, further experiences with injured bile ducts, 257, surgical problem of perampullary cancer, 370, internal fistulas of, 464, gall bladder disease among Filipinos, with report on ascariasis of, 561
- Bilirubin, Serum, during course of icterus, 172
- Bladder, Ureterointestinal implantation and total cystectomy for cancer, 80, attempt at classification of tumors of, 81, diagnosis and therapeutic indications in tumors of, 82, relation of transitional cell buds, Golgi apparatus, and mitochondria to carcinoma of, 82, our initial implantation of total cystectomy, 83, new method of physematosa, 188, condition of, and ureters after nephrectomy for renal tuberculosis, 188, tumors of diverticula of urinary, 188, extravascular radium therapy in cancer of, 189, incontinence of urine caused by dysplasia of vesical neck, with paradoxical vesicoureteral reflux, nephroureterectomy and Young's operation, classification of urinary incontinence, 190, report of clinical Cancer Research Committee of British Empire Cancer Campaign, 190, occlusion of orifice of, after suprapubic prostatectomy, 272, cystitis glandularis, 273, obstruction of neck of, review of 508 cases treated by endoscopic resection, 275, cystectomy in male, significance of combined prostatectomy and vesiculocystectomy with reference to sexual function, 384, artificial urinary, 385, complete excision of pelvic viscera in male for advanced carcinoma of sigmoid invading urinary, 463, operative treatment of female "stress" incontinence, 477, transurethral resection for neurogenic, 490, indications, limitations, technique, and results of bloodless surgery (instrumentation) in treatment of vesical calculi, lithotripsy and operative endoscopy, 490, clinicoexperimental study of action, prolonged for years, of some amines on, of workmen, 491, mucus secreting adenocarcinoma of, 491, biopsy and end results of tumors of, 582
- Blalock-Taussig operation for morbus coeruleus, 238
- Blastomycosis, Infestation with paracoccidioides brasiliensis, anatomopathologic study and fluorescent coloration of parasite, 414, special study of Jorge Lobo's variety, 609
- Blindspot syndrome, 219
- Blood, Anemia following resection of intestine, 56, biological significance of protein concentration and changes

SUBJECT INDEX—ABSTRACTS—VOLUME 89

- occurring in gynecologic laparotomies, 68, simple method of estimating flow of, with reference to circulation in pedicled skin flaps and tubes, 98, effect of caronamide with heparin on coagulation of human, 103, primary splenic neutropenia, specific indication for splenectomy, 174, venous block of spleen and splenomegalic inhibition of bone marrow, 258, hemolytic disease of newborn, 267, results of therapy of erythroblastosis with exchange transfusions, 268, use as controls of various hematologic values and in par-ticular plasma protein level after surgical interven-tion, 298, determination of, and estimation of loss of, during surgical operations, 301, rh groups of, and their clinical effects, 394, hemophilia, clinical study of 40 patients, 394, supply of, in cross leg pedicle flaps, 396, sickle cell anemia in adults, roentgenographic findings, 409, roentgenologic changes in sickle cell anemia, 413, venous pressure in relation to volume of, in man, 413, target and resistant red cells in pregnancy, posthe-morrhagic anemias and, of umbilical vein, 483, specific gravity, hemoglobin, hematocrit, and proteins in, of fetuses in various months of intrauterine develop-ment, 484, experimental contribution to study of chloridemia in rabbits with puncture of chloride cen-ter, 493, critique of methods for its determination, prothrombin, clinical and roent- and their clinical significance, 501, clinical and roent-gen manifestations of erythroblastosis fetalis, 516, hematological effects of ionizing radiations, 518, indi-cations and results of splenectomy, 562, studies on burns, effect of heparin on circulating plasma of, and proteins in experimental burns, 597, use of fluorescein in estimating flow of, in pedicled skin flaps and tubes, 602
- Blood pressure, Results of specifically co-ordinated plan of medical and surgical treatment of essential hyperten-sion, 35, personal experiences with surgical treat-ment of unilateral nephropathy in hypertension, 271, venous pressure in relation to blood volume in man, 413, evaluation of treatment of hypertension, 440, medical and surgical treatment of hypertension, 542, combined splenectomy and portacaval shunts in portal hypertension, 564
- Blood transfusions, Results of therapy of erythroblastosis with exchange, 268, role of massive, in management of ruptured uterus and other serious obstetric shock, 483, use of replacement, in diseases other than hemolytic disease of newborn, 502
- Blood vessels, Arteriovenous fistula of lung treated by liga-tion of pulmonary artery, 39, operation of stenosis of aortic isthmus 6 cm in length, 42, surgical treatment and physiopathology of coarctation of aorta, 43, thoracoabdominal approach for portacaval anastomo-sis, 46, treatment of varicose veins by ligation of saphenous vein and injection in both central and peripheral directions according to Olssonqvist's method, 92, attempt to evaluate different modern methods for prevention and treatment of thromboembolism, 94, rate of flow of venous, in legs, measured with radio-active sodium, 198, restoration and preservation of arterial continuity following trauma, 198, diagnosis and treatment of vascular obstruction, 198, histo-pathologic contribution to our knowledge of Buerger's disease (obliterating thromboangitis), 199, treatment for coarctation of aorta, 239, vascular congestion and hyperemia, 262, arteriography in pathologic stumps, role of arterial circulation in genesis of trophic dis-turbances, 295, multiple arterial emboli, 3 successful embolotomies in case of bacterial endocarditis, 295, treatment of varicosities of lower extremities, 296, further consideration of surgical management of chron-ic varicose ulcers, 296, peripheral disease of, in lungs, 303, should we continue to use thorotrast for angio-graphic purposes, 307, collateral circulation, 310, ex-vascularization of human stomach, preliminary note on shunting effect of trauma, 362, arterial injuries, analysis of immediate and late results of arterial injury, based on military experience, 393, postphlebotic se-quelae, 393, tissue-culture evaluation of viability of, stored by refrigeration, 394, wounds of extremities, 397, effect of vasoconstrictors upon duration of spinal anesthesia, controlled study in man, 404, angiocardi-ographic measurement of normal great, 410, aid of arteriograms in diagnosis and treatment of inferior cranial aneurysms, 410, surgical anatomy of inferior mesenteric artery and Sudeck's point, 454, vascular-ization of human stomach, 456, syndrome of gradual occlusion of large arteries with polythene and tantalum, 500, experimental production of gradual occlusion of large arteries with polythene and tantalum, 500, vascularization of cornea, its experimental induc-tion by small lesions and new theory of its pathogene-sis, 532, surgical treatment of patent ductus arteriosus, 545, surgical treatment of persistent ductus arteriosus, 545, operative handling of aortic coarctation, 546, case of aneurysm of aorta after resection for coarctation cured by excision, 546, revascularization following experimental mesenteric vascular occlusion, 551, ob-servations on Raynaud's disease, report of 35 cases, 594, arterectomy for arteritis obliterans of lower extremities, 594, obstruction of superior vena cava, review of literature and report of 2 personal cases, 594, major surgical operations in presence of bundle branch block, 597, experimental study of fatal pul-monary embolism, 597, arteriographic demonstration of collaterals between internal and external carotid arteries, 605
- Bone, Estrogens and formation of, in human female, 89, multiple osteogenic sarcoma, 205, osteoid osteoma, 282, granuloma of, 282, 3 cases of osseous metaplasia of cytogenous stratum of endometrium, remarks on pathogenesis, 380, surgical treatment of osteoarticular tuberculosis, 387, delayed autogenous graft of, in treat-ment of congenital pseudarthrosis, 387, essential cysts and giant-celled tumors of, 495, clinic and pathologic anatomy of fracture, pseudarthrosis and malacia of navicular, 499, sarcomas of, 515, renal and osseous lesions, 578, dyschondroplasia with special considera-tion of its unilateral form (Ollier), 586
- Bones, End results of excision of carpal, 195, open reduction and internal fixation of fractures of long, 289, avascular necrosis of large segmental fracture fragments of long, 390, osteoporosis following burns, 402, polyostotic fibrous dysplasia (Albright's syndrome) and its com-parison with dyschondroplasia (Ollier's disease), cor-relation of roentgenological and pathologic findings, 408, osteitis fibrosa disseminata, 495
- Bowen's disease of vulva, 568
- Brachial plexus, Traction injuries of, in adults, 346, open wounds of, 440
- Brain, Neurological surgery through years of World War II, collective review, 1, hypertensive syndrome due to craniovertebral malformations, clinical, radiologic, and neurosurgical observations, 34, delays and errors in diagnosis of tumor of, 34, transorbital leucotomy, 34, modern surgical treatment of acute subdural abscess, 149, diagnosis of focal epilepsy, 227, absence of head-aches in certain types of frontal lobe tumors, 227, giant adenomas of hypophysis, considerations on 2

- cases, 228, thorotrast pyrograms in cerebral abscess, 342, abscess of frontal lobe secondary to ethmoiditis, 342, tuberous sclerosis with cerebral neoplasm, 343, massive intraventricular epidermoid, review of literature and report of case, 343, diagnosis of chronic subdural hematoma in children and adolescents, 406, abscess of, 439, percutaneous cerebral angiography and cerebral abscess, 539, abscess of, due to *Clostridium perfringens* treated with penicillin, 530, study of chronic subdural hematoma, 539, multiple tumors of, 539, analysis of electroencephalographic findings in 40 cases of varied tumors of, electroencephalographic findings in meningiomas, 540, medulloblastoma, non-operative management with roentgen therapy after aspiration biopsy, 607
- Breast, Carcinoma of**, 37, surgical and radiation treatment of cancer of, 38 carcinoma of, results from statistical research, 152, carcinoma of, precancerous conditions of, 152, carcinoma of, prognosis in carcinoma of, 152, carcinoma of, discussion on carcinoma of, 153, carcinoma of, value of simple mastectomy and radiotherapy in treatment of cancer of, 153, carcinoma of, surgical aspect of carcinoma of, 154, plasma-cell mastitis, 232, multilobular hematoma of mammary gland, 232, statistical studies of role of histology in postoperative prognosis of mammary carcinoma, 233, edema of upper extremity in mammary cancer, 233, influence of pregnancy on cancer of, 234, radical mastectomy, 234, role of irradiation in management of carcinoma of, 307, mammary lipoma, 349, carcinoma of male mammary gland, 349, hormone treatment of inoperable carcinoma of, 349, researches on microscopic metastases of supraclavicular lymph nodes in carcinoma of, 349, mammoplasty for pendulous, 442, some enigmas associated with genesis of mammary cancer in mice, 443, testosterone propionate in treatment of cancer, 543
- Breath deliveries, Fetal mortality in**, 183
- Broad ligament, Peritoneal bodies and cysts of**, 472
- Bronchi, Analysis of variations of segmental, of right lower lobe of 50 injected lungs, 443, analysis of variations of segmental, of left lower lobe of 50 dissected, and 10 injected lungs, 445, amyloid tumors of larynx, trachea or, report of 15 cases, 538**
- Bronchiectasis, Disposal of bronchial stump in lobectomy and pneumonectomy for**, 353, its curative treatment by pulmonary resection, 446
- Bronchography, 512, incidents and accidents in**, 241
- Bronchostenosis of inflammatory origin, 6 cases, 350**
- Bronchus, Rupture of, due to external chest trauma, report of 3 cases with recovery, 38, traumatic rupture of, with occlusion, 39, carcinoma of, 39, refinement of technique in cytologic diagnosis of tumors of, 237, adenoma of, 446**
- Brucella, Splenectomy in infection due to**, 63
- Buerger's disease, Histopathologic contribution to our knowledge of, (obliterating thromboangitis), 199**
- Burns, Nature of shift of plasma protein to extravascular space following, 208, osteoporosis following, 402, treatment of, 504, management of severe, 505, rapid elimination of eschar of, by use of pyruvic acid, 508, structure of liver in fatal, 520, studies on, effect of heparin on circulating blood plasma and proteins in experimental, 597, observations on treatment of dorsal, on hand, 598, role of nervous system as cause of immediate general symptoms following, 609**
- kidney and ureteric, 487, branched kidney, 487, urinary citrate excretion in patients with renal, 487, indications, limitations, technique, and results of bloodless surgery (instrumentation) in treatment of vesical, lithotripsy and operative endoscopy, 490, of urinary tract, 585**
- Calculus, Pancreatolithiasis, 62**
- Canal of Schlemm, Further gonioscopic studies on**, 532
- Cancer, Of larynx, statistical study, 33, of breast, 37, surgical and radiation treatment of, of breast, 38, bronchial, 39, of superior mediastinal segment of esophagus, 44, end results in treatment of, of stomach, 53, evaluation of conservative resection with end to-end anastomosis for, of rectum and lower sigmoid colon, 56, of anal canal, 58, radiologic diagnosis of uterine, 65, primary, of fallopian tube, clinical and pathologic study with personal contributions, 66, observations on delay period in diagnosis of pelvic, 68, ureterointestinal implantation and total cystectomy for, 80, relation of transitional cell buds, Golgi apparatus, and mitochondria to, of bladder, 82, of urachus, 86, irradiation in, of tongue, 100, roentgen treatment of, of larynx by concentration method, 100, carcinogenic and anticarcinogenic substances, 103, colonic and proctologic disease, collective review, 105, of larynx, 147, of breast, results from statistical research, 152, of breast, precancerous conditions, 152, of breast, prognosis, 152, of breast, discussion, 153, of breast, value of simple mastectomy and radiotherapy in treatment, 153, of breast, surgical aspect, 154, distribution of gastric changes accompanying gastric, in various locations, 166, selection of patients and anastomotic procedures for, of rectum and rectosigmoid, 171, vaginal cytology in uterine, 175, of cervix, 176, present-day status of noninvasive cervical, 176, controversial factors in management of, of cervix, 177, desirable management of fundal, 177, role of surgery in treatment of, of cervix, 178, implantation of secondaries from renal, (hypernephroma) within ureteral lumen, 186, extravascular radium therapy in, of bladder, 189, of prostate and its hormonal management, 189, report of clinical research committee of British Empire Campaign against, 190, developing in sebaceous cysts, 208, of tongue, 224, statistical studies of role of histology in postoperative prognosis of mammary, 233, edema of upper extremity in mammary, 233, influence of pregnancy on, of breast, 234, studies on lung abscess, lung abscess and bronchial, 235, bronchogenic, of middle lobe and segmentary bronchitis, 237, importance of level of lesion in prognosis and treatment of, of rectum and low sigmoid colon, 252, discussion on radical excision of, of rectum with conservation of sphincters, 253, surgical treatment of, of rectum and colon, 254, primary, of liver, hepatoma, 256, of uterine cervix, 260, value of postoperative irradiations of, of uterus, 261, modifications of rectal mucosa in, of uterine cervix, 263, cells of, in prostatic secretions, 274, treatment of, of penis, 278, role of irradiation in management of, of breast, 307, intravaginal roentgen therapy in, of cervix uteri, 308, review of 10 years' experience with transvaginal roentgen therapy, 308, of cervical stump, 309, of male mammary gland, 349, hormone treatment of inoperable, of breast, 349, researches on microscopic metastases of supraclavicular lymph nodes in breast 349, diagnosis of, of lung, 354, of lung with intracranial metastasis, successful removal of metastatic and primary lesions, 354, surgical treatment of, of colon, 367, surgical problem of perianillary, 370, of pancreas, 371, role of surgery in treatment of, of cervix, 374, discussion of certain findings at autopsies of patients with, of uterus, 375, of ureter, 383, detection of gastric, by photofluorographic methods, introduction, equipment, and design, 407, place of deep external x ray irradiation in treatment of, of cervix by long element needles, 411, probable trends in irra-**
- CAFFEINE test, Provocative, in glaucoma, 29**
- Calcinosis, Interstitial, 516**
- Calculi, Etiological and therapeutic experiences concerning**

SUBJECT INDEX—ABSTRACTS—VOLUME 89

- diation treatment of, of cervix uteri with improved expanding type of radium applicator, 411, problem of, 415; of thyroid gland, 438, enigmas associated with genesis of mammary, in mice, 443, primary bronchogenic, correlation of recent literature with 131 proved cases, 447, alveolar cell, of lung (pulmonary adenomatosis jagzickte?), 448, survival in primary, of lung, 448, linitis plastica and stomach cured by resection, of stomach (Krompecher disseminating sclerosing, of stomach (Krompecher disseminating Konjetzky fibrous), 459, clinical notes, 3 cases of, of stomach cured by resection, of sigmoid invading pelvic viscera in male for advanced, of distal urinary bladder, 464, unsuspected cervical, in gynecological patients, 470, results of treatment of, of male urethra, 491, basal-cell, 520, of cervix, 1948 survey of treatment in United States and Canada, collective review, (1936-1941), 471, of vulva, 474, primary, of male urethra, 491, antrum, report of 9 cases, with 10 year survey of literature, 535, testosterone propionate in treatment of, of breast, 543, surgical treatment of, of distal quarters of thoracic esophagus and cardia, 548, case of carcinosarcoma of esophagus, 549, treatment of, of rectum with reference to preservation of sphincter mechanism, 560, primary, of liver, 25 year study, 561, clinical classification of, of endometrium, 567, reactions to x-ray and radium therapy in treatment of, of uterine cervix, 607, radium therapy in, of female urethra, 608
- Carcinogens, Lack of extractable, in skin of patients with multiple precancerous keratoses of actinic origin, 475
- Carcinosis, Pseudoscirrhus, of liver, 368
- Caronamide, Effect of, with heparin on coagulation of human blood, 103
- Cartilage, Diffuse inflammation of, case report of hitherto unreported entity, 87, reconstruction of auricle with diced grafts of, in vitalium ear mold, 338, polyostotic fibrous dysplasia (Albright's syndrome) and its comparison with dyschondroplasia (Ollier's disease), correlation of roentgenological and pathologic findings, 408, prefabricated autogenous, for ear, 430, dyschondroplasia with consideration of its unilateral form (Ollier), 586
- Cataract, Rupture of zonule in intracapsular extraction of, new method, 145
- Cauda equina, Effect of injury to spinal cord and, on sexual potency of men, 151
- Caudal anesthesia, anatomic reasons for failure of, 404
- Causalgia, Syndromes of, 541
- Cecum, Volvulus of, 367, volvulus of, with review of 100 cases in literature and report of 6 new cases, 367
- Cells, Studies in growth of, 104
- Cervical plexus, Injuries of, 345, resection of clavicle in lesions of, 345
- Cervix, Newer methods in management of abnormal, 175, adenocarcinoma of, and of stump of, 176, carcinoma of, 176, present-day status of noninvasive carcinoma of, 176, controversial factors in management of carcinoma of, 177, role of surgery in treatment of carcinoma of, 178, wide conization of, 260, pregnancy in, 478
- Cesarean section, Modern indications for, 181, in Dublin, 266, in contaminated cases, résumé of 1,138 observations, 378, extraperitoneal, in profoundly infected patient, 481, vaginal delivery following, 482
- Chemistry, Ménière's syndrome, its relation to, etiologic study, 336
- Chemotherapy, Neurological surgery through years of World War II collective review, 1, role of, in wounds and surgical infections, study of significance of gram-negative pathogens in fresh trauma and chronic infections, 96, colonic and proctologic disease, collective review, 105, comparison of efficacy of therapeutic agents in treatment of experimentally induced diffuse peritonitis of intestinal origin, 312
- Children, Colonic and proctologic disease, collective review, 105, refractures in, 195, follow up results of fractures of femoral shaft in early and late infancy, 292, tachycardia in, during anesthesia, 301, convulsions under anesthesia in, 403, hip lesions of infants and, seen at Newington Home and Hospital for Crippled, 408, malignant disease in infants and, 610
- Chloridemia, Experimental contribution to study of, in rabbits with puncture of chloride center, 493
- Chlorides, Observations on behavior of glucose, proteins and, in blister fluids, with regard to surgical interventions, 503
- Cholecystectomy, Late results of, factors involved in failures and in recurrences, personal experience of Naples Clinic, 59, recurrences after, 257, observations on technique of subserosal, 369, role of roentgenology in prevention and diagnosis of postoperative pain syndromes in, 465
- Cholecystitis, Nervous hypergenesis of, 58, parasitic, 368
- Cholecystitis emphysematosa, 369
- Cholecystography, Response of gall bladder to Benassi-Vitale's water test in course of, after gastric resection, 604
- Choledochus, Traumatic rupture of, associated with acute hemorrhagic pancreatitis and bile peritonitis, 60
- Cholesteatoma, Modified radical mastoidectomy, preservation of matrix of, method of making flap in endaural technique, 338
- Chondrodystrophy fetalis, 74
- Choroiditis, Traumatic, review of literature and report of 10 cases, 533
- Chylorhax, Traumatic, 45, 159
- Chyluria, Case of, of right kidney, 270
- Circulation, Rate of flow of venous blood in legs, measured with radioactive sodium, 198, evaluation of lesser circulation as portrayed by roentgenogram, 305, collateral, 310, experimental study of collateral coronary, produced by cardiopneumonoxy, 356, studies of, of anesthetized patients by new method for recording arterial pressure and pressure pulse contours, 403
- Cirrhosis, Use of portacaval anastomosis in portal, 560
- Clavicle, Case report of bilateral cystic lesion of, with evidence of typical cysts, 284 resection of, in lesions of cervical plexus, 345
- Clostridium perfringens, Abscess of brain due to, treated with penicillin, 539
- Clostridium welchii, Studies in virulence of, 414
- Clubfeet, Open or bloodless treatment of, 589, operative treatment of, in older children and adults, 590
- Colitis, Surgery of complications of ulcerative, 57, etiology of chronic ulcerative, 170, surgical treatment of chronic ulcerative, 170, involvement of ileum in chronic ulcerative, 249, ulcerative, 249, idiopathic ulcerative, 250, present concepts in ulcerative, 554, ulcerative, ileosotomy life, 555, ulcerative, clinical features, diagnosis, and treatment, 556
- Collapse therapy, Experimental and clinical study of, with fibreglas wool and fabric, 543
- Collective review, Neurological surgery through years of World War II, 1, colonic and proctologic disease, 105, surgical jaundice, 209, evaluation of principles concerned in management of obstruction of bowel, 417, carcinoma of cervix, 1948 survey of treatment in United States and Canada, 521, ovarian tumors in pregnancy, 525

- Colon, Evaluation of conservative resection with end-to-end anastomosis for carcinoma of rectum and lower sigmoid, 56, proctologic disease and disease of, collective review, 105, malignant tumors of, and rectum, 170, volvulus of sigmoid, in course of pregnancy of 7 months, 180, surgical treatment of polyps of large intestine, 247, polypoid lesions of, and rectum, 251, surgical treatment of cancer of rectum and, 254, retroperitoneal lymphangioma with fistula in, demonstrated by roentgenography, 259, volvulus of cecum, 367, volvulus of cecum, with review of 100 cases in literature and report of 6 new cases, 367, myenteric plexus in congenital megacolon, study of 11 cases, 367, surgical treatment of cancer of, 367, wounds of, and rectum, critical analysis of current methods of surgical treatment with emphasis on details of surgical technique, 368, internal strangulating obstruction of bowel, collective review, 417, polypoid lesions of terminal portion of, 462, operative treatment of carcinoma of distal, and rectum, 464, technique and results of anastomosis between ureter and, by extraperitoneal route, 489, discussion on Hirschsprung's disease, 558, volvulus of sigmoid loop, 559, critical and experimental studies of sutures of, in dogs, 559, genitocolitic syndrome, 570
- Cornea, Symposium, transplantation of, selection of cases, 25, transplantation of, technique, 25, transplantation of complications, 25, transplantation of, physiopathology, 26, transplantation of, results, 26, infection of, due to herpes simplex, experimental study, 144, lattice type of hereditary degeneration of, report of 5 cases, 1 of which occurred in child of 2 years, 144, vascularization of, its experimental induction by small lesions and new theory of its pathogenesis, 532, pharmacology and toxicology of, contemporary concepts, 533
- Corpus luteum, Excision of, during pregnancy and effect on production of progesterone, 180
- Cough, Fracture due to, in late pregnancy, 290, fracture of ribs due to, 291
- Coxa vara, Developmental, 192, congenital, 285, morphology of congenital, 587
- Cranial nerves, Observations upon loudness recruitment phenomenon with reference to diagnosis of disorders of internal ear and eighth, 31
- Cranioplasty, Late complications following, with alloplastic plates, 150
- Cryptorchidism, Malignancy in, 584
- Culdoscopy, 569
- Curare, Traumatic shock and, 206, our experience with endotracheal anesthesia with, and artificial respiration, 600
- Curling's ulcer, Observations of, 403
- Cyclodialysis, Replacement of air in, 146
- Cyst, Choledochus, associated with congenital atresia of bile ducts, 60, 2 cases of enterogenous, 63, significance of enlargement of ovary with respect to treatment, 65, tumor and superimposed, of urachus, 86, epithelial tumors associated with developmental, of maxilla, 141, gastric, of mediastinum, 158, carcinoma developing in sebaceous, 208, report of case of bilateral lesion of clavicle with x-ray evidence of typical, 284, Rathke's cleft and its, 342, benign, of superior maxilla with reference to, of maxillary sinus, clinicopathologic study of 30 cases, 435, peritoneal bodies and, of broad ligament, 472, essential, of bone and giant-celled bone tumors, 495, ovarian tumors in pregnancy, collective review, 525
- Cystectomy, Our initiation into field of total, 83
- Cysticercosis, Ocular, 335
- Cystitis emphysematosa, 188
- DEAFNESS, Hydrodynamics and hearing, operative relief of otosclerotic and nonotosclerotic, and its relationship to hydrodynamic hypothesis of hearing, 431
- Deaths, Pathologic findings in some, during anesthesia, 403, injuries and, from lightning, 504
- Decubitus ulcers, Neurological surgery through years of World War II, collective review, 1, pressure sores in paraplegic patients, 509
- Deformities, Roentgenologic, of pyloric portion of stomach with absence of surgical and pathologic findings, 204, paralytic equinovarus, of foot, 387
- Dehydration, Parenteral use of water, dextrose, electrolytes, fat, and vitamins, 94, wounds of extremities, 397
- Detergents, Experimental study of wound healing, new technique and study of effect of, and of antacid on wound healing, 206
- Dextran, As plasma substitute, 310, as plasma substitute, 310
- Diabetes insipidus and pregnancy, 571
- Diabetes mellitus, Pregnancy complicated by, 264
- Diagnosis, Observations on delay period in, of pelvic cancer, 68, ultimate resort in, of pregnancy, 71, and therapeutic indications in tumors of bladder, 82, radioactive iodine as aid in, of intrathoracic goiter, 102, of sagittal suture, chin and ear in posterior occiput to brow presentations, 181, and treatment of vascular obstruction, 198, of focal epilepsy, 227, of gastric neoplasms, 245, evaluation of principles concerned in management of trauma to kidney, 313, of carcinoma of lung, 354, of chronic subdural hematoma in children and adolescents, 406, internal strangulating obstruction of bowel, collective review, 417
- Diaphragm, Pyogenic empyema with extension below, 544
- Diaphragmatic hernia, Strangulating, of liver, 46, strangulation of, 453, right retrosternal, 514
- Diastase, Chronic recurrent pancreatitis, clinical and laboratory aspects, serial levels of, in serum following prostigmine stimulation, 370
- Diathermy, Successful treatment of recurring retinal hemorrhage and retinitis proliferans with, report of case, 429
- Dicumarol, Experimental study on use of, in arterial surgery, 295, danger of treatment with, in pregnancy, 483
- Diethylstilbestrol in prevention and treatment of complications of pregnancy, 73
- Disinfection, Rapid, of clean, unwashed skin, 200
- Dislocation, Experiences and results of various operations for habitual, of shoulder, 89, traumatic posterior (retroglenoid), of humerus, 390, arthroplasty in cases of congenital, and subluxation of hip in children, 194, acute anterior, of shoulder, 288, treatment of recent, and fracture dislocations of shoulder, 288, treatment of true congenital, of hip, 291, etiology of congenital, of hip, 586, congenital dysplasia of hip joint, relationship between congenital subluxation and congenital, 587, late results of operative treatment of recurrent, of patella, 591
- Disodium succinate, Study of pentothal sodium anesthesia and critical investigation of use of, as antidote, 301
- Diverticula, Retained food remnants in esophageal, resembling tumor and dysphagia in cases of small esophageal, at bifurcation level, 357, of stomach, report of 30 cases and review of literature, 363, urethral, in female, clinical study, 476
- Dosage, Lethal, of total body x-ray irradiation in swine, 412
- Drainage, Continuous suction, 560
- D-tubocurarine, Treatment of tetanus, 97
- Ductus arteriosus, Surgical treatment of persistent, 545, surgical treatment of patent, 545

SUBJECT INDEX—ABSTRACTS—VOLUME 89

1X

- Duodenum, Palliative gastrectomy in cases of ulcer of, 52, operative diagnosis of indurations of, and pancreas, 61, experimental research on behavior of stump of, following exclusion resection, 247, surgical therapy of ulcer of, 366, management of bleeding ulcers of, 461, development of deep ulcer of, 552
- Dura mater, Purulent pachymeningitis, 149
- Dust, Air infection with, liberated from clothing, 207
- Dysgerminoma of ovary, 66
- Dystocia, In face presentation, 377, due to obstructing tumors, 377
- E**AR, Observations upon loudness recruitment phenomenon, with reference to diagnosis of disorders of internal, and eighth nerve, 31, Lempert decompression operation for hydrops of endolymphatic labyrinth in Ménière's disease, 31, test findings before and after fenestration of labyrinth, 147, tuberculosis of nose, throat, and, treated with streptomycin, report of 12 cases, 222, visualization of cavum tympani and auditory canal with opaque medium, experiments on dogs, 303, Ménière's syndrome, its relation to chemistry, otologic study, 336, surgery of chronically discharging, 337, Lempert endaural subcortical mastoidectomy for cure of chronic persistent suppurative otitis media, 337, reconstruction of aural with diced cartilage grafts in vitallium mold of, 338, modified radical mastoidectomy, preservation of cholesteatoma matrix, method of making flap in endaural technique, 338, prefabricated autogenous cartilages of, 430, microtic, 431, hydrodynamics and hearing, operative relief of otosclerotic and nonotosclerotic deafness and its relationship to hydrodynamic hypothesis of hearing, 431, histopathologic investigations on localization, number, activity, and extent of otosclerotic foci, 432, acoustic function before and after operations for otosclerosis, 433, Popper's operation for diseases of transtympanic approach and fenestration, current technique, 434, antibiotics in treatment of diseases of nose, throat and, 534, experiences with penicillin treatment of acute otitis media, 534, vestibular function prior to and following operation for otosclerosis, 535, biochemical conditions in patients with otosclerosis, 535, conditions of external auditory meatus and tympanic membrane in patients with otosclerosis, 535
- Eclampsia, Certain aspects of, 479
- Elbow, Patella cubiti, new method of treatment for its avulsion, 193, treatment of complicated inflammatory processes of articulation of, 289, arthroplasty of, 589
- Electrocution, Sequelae of, and infiltration of stellate ganglia, 396
- Elephantiasis, Congenital, 293
- Emboli, Multiple arterial, 3 successful embolectomies in case of bacterial endocarditis, 295
- Embolism, Management of venous thrombosis and pulmonary, following injury to extremities, 93, possibility of venous, in course of hysterosalpingography, 99, wounds of extremities, 397, experimental study of fatal pulmonary, 597
- Emetin and appendicitis 559
- Empyema, Exploratory thoracotomy in management of pleural, 242, pyogenic, with extension below diaphragm, 544
- Endometriosis, Complications of, 469, surgical treatment of, 469, ovarian tumors in pregnancy, collective review, 525, remarks on pathologic physiology of, on occasion of 3 observations of, of posterior vaginal vault, 567
- Endometrium, Three cases of osseous metaplasia of cytogenous stratum of, remarks on pathogenesis, 380, clinical classification of carcinoma of, 567
- Enema, New observations on oral opaque, of small intestines, 55
- Enteritis, Regional hypertrophic, at ileocecal bottleneck (Crohn's disease), 552
- Epidermoid, Massive intraventricular, review of literature and report of case, 343
- Epilepsy, Diagnosis of focal, 227
- Epithelioma of scrotum, 278
- Erythroblastosis, Results of therapy of, with exchange transfusions, 268
- Erythroblastosis fetalis, Clinical and roentgen manifestations of, 516
- Escherichia coli, Appraisal of oral streptomycin as intestinal antiseptic, with observations on rapid development of resistance of, to streptomycin, 167
- Esophagus, Benign stricture of, 43, bridging of defect of, by pedicled flap of lung tissue, 44, carcinoma of superior mediastinal segment of, 44, foreign body in thyroid following perforation of, 224, displacement of, into new diaphragmatic orifice in repair of paraesophageal hernia and hiatus hernia of, 240, surgical treatment of perforations of, 241, roentgenologic symptoms of injuries of, and stomach resulting from caustic poisons, 393, retained food remnants in cases of small diverticula, 357, treatment of mediastinitis from perforation of, at bifurcation level, 357, tuberculous fistula involving, 358, some rare anomalies of, 451, surgical treatment of megadolichoesophagus, esophagogastrostomy of necessity or on principle, 547, surgical treatment of carcinomas of distal three quarters of thoracic, and cardia, 548, carcinosarcoma of, 549
- Estrogens, And bone formation in human female, 89, clinical study of 1 methyl bisdehydroisynolic acid, new synthetic, 376
- Ethmoiditis, Abscess of frontal lobe secondary to, 342
- Extremities, Wounds of, 397
- Eye, Proptosis due to neuroblastoma of adrenal cortex (Hutchinson's syndrome), report of case, 24, allergic conditions of, keratitis rosacea, 24, allergic conditions of, migraine, 25, symposium on corneal transplantation, 25, technique, 25, complications, 25, physiopathology, 26, results, 26, anterior flap sclerotomy with basal iridencleisis, preliminary note, 26, studies in experimental ocular tuberculosis, effect of promin and promazole on experimental ocular tuberculosis in immune allergic rabbit, 27, bacitracin in ocular infections, 27, prognosis in uveal melanoma, 28, changes in ocular fundus associated with pheochromocytoma of adrenal gland, report of 3 cases, 28, provocative tests in glaucoma, 29, fascia of orbit, 141, horizontal concomitant strabismus, 141, operative treatment of vertical tropias, 142, implant of vitallium tube in treatment of stenosis of lacrimal duct, 142, intravitreal injections of penicillin, study on levels of concentration reached and therapeutic efficacy, 142, control of experimental infections of anterior chamber and of vitreous by subconjunctival and retrobulbar injections of crystalline penicillin in doses of 1,000,000 units, 143, distribution of penicillin in after injections of 1,000,000 units by subconjunctival retrobulbar and intramuscular routes, 143, controversial points in penicillin therapy of ocular diseases, 143, infection of cornea due to herpes simplex, experimental study, 144, lattice type of hereditary corneal degeneration, report of 5 cases, 1 of which occurred in child of 2 years, 144, rupture of zonule in intracapsular cataract extrac-

- tion, new method, 145, preliminary note on treatment of hypopyon ulcer with crystalline penicillin in adrenalin in doses exceeding 50,000 units injected by subconjunctival or retrobulbar routes, 145, miotic and antiglaucomatous activity of tetraethyl pyrophosphate in human, 145, preplacement of air in cyclodialysis, 146, symptoms of pulse in central retinal artery, 146, local anesthesia in ophthalmology, 146, ocular signs in head trauma, 216, in mongolism, 216, studies in experimental ocular tuberculosis, effect of promin and promizole in experimental ocular tuberculosis in normal rabbit, 217, fundus dystrophy with unusual features, late onset and dominant inheritance of central retinal lesion showing edema, hemorrhage, and exudates developing into generalized choroidal atrophy with massive pigment proliferation, 217, mycotic infection of, 217, motor block of extraocular muscles by deep orbital injections, 217, role of inheritance in glaucoma, 218, technique of goniotomy for congenital glaucoma, 218, necrosis of intraocular tissues, 218, use of pooled human vitreous, 219, retrolental fibroplasia, 219, scleromalacia perforans, report of case, 219, blind spot syndrome, 219, subretinal drainage in retinal detachment, 220, surgical treatment of retinal detachment, 220, retinoblastoma (retinal glioma) cured by radon seeds, report of case, 221, treatment of bilateral retinoblastoma, 221, ocular cysticercosis, 335, tumors of optic nerve, long survival in 3 cases of intracranial tumor, 336, experimental studies on pathogenesis and treatment of tuberculosis of, 428, diathermy cauterization of ciliary body for glaucoma, 429, successful diathermy treatment of recurring retinal hemorrhage and retinitis proliferans, report of case, 429, diagnosis of retinoblastoma, 429, vascularization of cornea, its experimental induction by small lesions and new theory of its pathogenesis, 532, further gonioscopic studies on canal of Schlemm, 532, penicillin as prophylactic against ophthalmia neonatorum, comprehensive study 532, pharmacology and toxicology of cornea, contemporary concepts, 533, traumatic choroiditis, review of literature and report of 10 cases, 533, ocular complications of temporal arteritis, 534
- F**ACE, Injuries of, followed by meningitis, with recovery, 32, gangrene of, following occlusion of posterior inferior cerebellar artery, 227, complications and sequelae of untreated fractures of bones of, and their treatment, 335, malignant disease of, and scalp, excision and repair, 532, operative restoration after paralysis of, 540
- Fallop's tetralogy, Angiocardiography in congenital heart disease of cyanotic type with pulmonic stenosis or atresia, observations on, and pseudotruncus arteriosus, 513
- Feet, Open or bloodless treatment of club, 589, operative treatment of clubfoot in older children and adults, 590
- Femur, Intracapsular fractures of neck of, follow up report of 130 patients treated by internal fixation with Smith Petersen nail, 88, fractures of neck of, 194, tuberculosis of greater trochanter and trochanteric bursae, 286, roentgenographic changes in nailed slipped capital epiphysis of, 291, treatment of necrotic head of, in adults, 292, intracapsular fractures of, treated with combined Smith Petersen nail and fibular graft, 292, follow up results of fractures of shaft of, in early and late infancy, 292, results of intertrochanteric osteotomy in pseudarthrosis of neck of, 388, attempts at prosthetic reconstruction of hip after resection of head of, 497 wedge osteotomy for fresh intracapsular fractures of neck of, 499 pinning for slipping of epiphysis of head of, 589
- Penestration Transmyapnic approach and, current technique 434
- Fetus, Extrauterine pregnancy exteriorized through persistent Malpighi Gartner canal with expulsion of skeletal remnants of embryo, 72, chondrodystrophy of, 74, diagnosis of sagittal suture, chin, and ear in posterior occiput to brow presentations, 181, kidney function in, 185, specific gravity, hemoglobin, hematocrit, and proteins in blood of, in various months of intrauterine development, 484
- Fever following splenectomy, 372
- Fibromyoma, Review of 445 pregnancies complicated by, 485
- Fibromyxochondrosarcoma of cervix uteri, 374
- Fibula, Conservative therapy of agenesis of tibia and, report of 5 clinical cases, 495
- Fingers, Treatment of open traumatism of hand in miners, 95
- Fistulas, Arteriovenous, of lung treated by ligation of pulmonary artery, 39, gastrojejunocolic, 163, procedures used in treatment of complicated, 169, anastomosis of external biliary, into gastrointestinal tract, 173, tuberculous esophagogastric, 357, internal biliary, 464, multiple aortointestinal, secondary to swallowed foreign body, 468
- Flatfoot, Etiology of peroneal spastic, 196
- Fluorescein, Use of, in estimating blood flow in pedicled skin flaps and tubes, 602
- Folliculin, Action of, and progesterone on water metabolism in pregnancy, 574
- Foot, Study of longitudinal arch of, 90, value of transmetatarsal amputations in management of gangrene of toes, 93, etiology of peroneal spastic flat, 196, congenital elephantiasis, 293, paralytic equinovarus deformities of, 387, removal of base of proximal phalanx in hallux rigidus, 591, isolated fracture of tarsal scaphoid, end result of scaphoidectomy, 592
- Foreign bodies, Neurological surgery through years of World War II, collective review, 1, in thyroid following perforation of esophagus, 224, surgical problems of retained intrathoracic, 452, multiple aortointestinal fistulas secondary to swallowed, 468
- Fractures, Intracapsular, of neck of femur, follow up report of 130 patients treated by internal fixation with Smith Petersen nail, 88, general conceptions of pseudarthrosis, statistical considerations, 89, study of results obtained in treatment of, of lower end of radius in insured persons in Finland, 194, of neck of femur, 194, partial patellectomy in, of knee, 195, in children, 195, of orbital floor, 217, treatment of recent dislocations and of, with dislocations of shoulder, 288, open reduction and internal fixation of, of long bones, 289, treatment of, of metacarpals, 290, from coughing in late pregnancy, 290, cough, of ribs, 291, intracapsular, of femur treated with combined Smith Petersen nail and fibular graft, 292, follow up results of, of femoral shaft in children and in early and late infancy, 292, complications and sequelae of untreated, of facial bones and their treatment, 335, avascular necrosis of large segmental fragments in, of long bones, 390, indication for operative treatment of, of proximal portion of upper arm, 390, follow up results of surgical treatment for nonunion of carpal scaphoid bone, report of 19 cases 391, management of intracapsular hip, 391, comminuted and segmental, of leg, 391, treatment of malleolar, according to Lauge Hansen's method, preliminary results, 392, wounds of extremities, 397, internal wire immobilization of, of jaw, 428, clinical and pathologic anatomy of pseudarthrosis, malunion of articular bone and, 499, wedge osteotomy for fresh intracapsular, of neck of femur, 499 importance of intramedullary nailing for treatment of pseudarthrosis, 591, comparative

SUBJECT INDEX—ABSTRACTS—VOLUME 89

xi

study of methods of treatment of diaphyseal, of leg, 592, isolated, of tarsal scaphoid, end result of scaphoidectomy, 592
Freyer method, Sixty five prostatectomies according to, 277

GALL bladder, Nervous hypergenesis of cholecystitis, in failures and in recurrences, factors involved at Naples Clinic, 59, recurrences after cholecystectomy, 257, parasitic cholecystitis, 368, cholecystitis emphysematosa, 369, observations on technique of subserosal, 369, role of roentgenology in prevention and diagnosis of postoperative pain syndromes in cholecystectomies, 465, case of tuberculosis of, 561, disease of, among Filipinos, with report on ascariasis of biliary tract, 561, response of, to Benassi-Vitale's water test in course of cholecystography after gastric resection, 604

Gallstone, Silent, 10 to 20 year follow up study of 112 cases, 59

Gangrene, Value of transmetatarsal amputations in management of, of toes, 93, plaster of paris as source of infection in tetanus and gas, 207, chronic progressive infectious, of skin, 208, of face following occlusion of posterior inferior cerebellar artery, 227, of penis, 273, question of, following popliteal injury, 297, amputation for, due to occlusive arterial disease, 596

Gas, Occurrence of sensation of stoppage of, in acute obstruction of ileum, 168
Gastrectomy, Partial, for peptic ulcer, 51, palliative, in cases of duodenal ulcer, 52, mechanism of gastroduodenal anastomosis during early postoperative period following, 365

Gastritis, Pseudoulcerative, 244

Gastroenterology and surgery, 64
Gastrointestinal tract, Intrapertoneal injury of hollow viscera due to nonpenetrating wounds, 48, physiological aspects of vagotomy, 53, motility of, following vagotomy and use of urecholine for control of certain undesirable phenomena, 54, study of arterial circulation at angle of duodenum, jejunum, and first intestinal loop, 55, anastomosis of ileum to lower part of rectum and anus, report on experiences with ileorectostomy and ileoproctostomy, with reference to polyposis, 56, spindle cell tumors of, 101, peripheral sensorial innervation of, 161, argentastinoma of, 165, anastomosis of external biliary fistula into, 173, argentastinoma of, with report of 11 cases, 361, lymphosarcoma of, with report of 21 cases, 361, intestinal obstruction, indications for surgical treatment, 365, internal strangulating obstruction of bowel, collective review, 417, massive hematemesis, 454, neurinoma in, 455, contribution to recognition of severe complications of neurofibromatosis of, 456, on operative treatment of gastric and duodenal ulcer at District Hospital, Hämenelinna, Finland, 458, continuous suction drainage, 560, advantages of end-to-end anastomoses with separate sutures in surgery of, 560

Gastropexy, New operation for, 551

Genital organs (female), Two cases of vaginal atresia observed in duplex anomalies of genitalia, 67, newer concepts of menstruation, 67, preliminary results of streptomycin therapy in tuberculosis of peritoneal cavity and of adnexa in female, 68, sterility in Finnish women with reference to causes and prognosis, 68, 2 cases of pregnancy in double uterus, 71, colonic and proctologic disease, collective review, 105, torsion

of organs and of tumors of, clinical contribution, 179, vascular congestion and hyperemia, 262, surgical treatment of prolapse of, 262, 2 cases of benign connective tissue tumor of female external genitalia, 473, vascular congestion and hyperemia, etiology and therapy, 474, vascular congestion and hyperemia, clinical aspects of congestion fibrosis syndrome, 474, histophysiology of sexual zone of adrenal cortex, 475, urethral diverticulum in female, clinical study, 476, late results of Re-voltella's anterior hysterodoligamentopexy, 568, effects of various estrogenic preparations, changes in vaginal mucosa and general status of climacteric women following injection of aqueous suspensions of estrone and estradiol, 569, culdoscopy, 569, genitocolic syndrome, 570

Genital organs (male), Blood loss in open prostatic surgery, 83, colonic and proctologic disease, collective review, 105, effect of injury to spinal cord and cauda equina on sexual potency of men, 151, report of Clinical Cancer Research Committee of British Empire Cancer Campaign, 190, perineal prostatectomy today, 275, retro-pubic prostatectomy, 276, 65 prostatectomies according to Frey's method, 277, diagnosis of internal genital tuberculosis in male by roentgenograms, 305, extirpation of granulomatous prostate, 492, radical perineal prostatectomy, 492, right inguinal and iliac sarcomatoid myxoma metastasized from previous remote epididymal blastic phase, 494, retropubic prostatectomy, 583

Genitourinary system, Cystectomy in male, significance of combined prostatoseminal vesiculocystectomy with special reference to sexual function, 384, treatment of tuberculosis with streptomycin, 190, streptomycin in urogenital infections, 279, Barge Bourgain's reaction in tuberculosis of, 385, streptomycin in tuberculosis of, 585

Glands, Carcinoma developing sebaceous cysts, 208
Glaucoma, Anterior flap sclerotomy with basal iridencleisis, preliminary note, 26, provocative tests in, 29, pressor test for, 30, role of inheritance in, 218, technique of goniotomy for congenital, 218, diathermy cauterization of ciliary body for, 429

Glossopharyngeal nerve, Neuralgia of, extracranial neurectomy, 228

Glucose, Observations on behavior of chlorides, proteins and, in blister fluids with regard to surgical interventions, 503

Goiters, Radioactive iodine as diagnostic aid for intra-thoracic, 102, contribution on 564 and 543 operations for, performed in 1946, 340, comparison of thymic hyperplasia in myasthenia gravis and exophthalmic, 358, nontoxic nodular, 437, treatment of thyrotoxicosis, 536

Grafts, Concept and techniques of dermoepidermal, 302
Granuloma of bones, 282
Gynandroblastoma of ovary, 261
Gynecologist, Ureter, the urologist and the, 475
Gynecology, Radiodiagnosis in, and obstetrics, editor's note, 380

HAMARTOMA, Roentgenologic significance of, of lung, 204
Hand, Tenosynovitis of extensor carpi ulnaris tendon sheath, 87, treatment of open traumatism of, in fingers, 95, use of penicillin in open injuries of, and fingers, 209, restoration of grasping function following loss of all five digits, 311, transfer of metacarpal, 388, tendon transfers and arthrodeses in combined median and ulnar nerve paralysis, 589, some observations on treatment of dorsal burn on, 598

INTERNATIONAL ABSTRACTS OF SURGERY

- Harelip and palatine fissure, 222
- Head, Ocular signs in trauma of, 216, ligation of carotid arteries for advanced malignant neoplasms of, 344, ocular complications of temporal arteritis, 534
- Headaches, Absence of, in frontal lobe tumors, 227
- Healing, Experimental study of, of wounds, new technique and study of effect of detergents and of antacid on, of wounds, 206, effect of injury of, of wounds, 311, of wound as biologic phenomenon, 609
- Hearing, Hydrodynamics and, operative relief of otosclerotic and nonotosclerotic deafness and its relationship to hydrodynamic hypothesis of, 431, acoustic function before and after operations for otosclerosis, 433
- Heart, Closure of defects in cardiac septa, 40, surgery of, 40, surgical treatment of mitral stenosis, valvuloplasty, 41, chronic constrictive pericarditis, study of 53 cases, 41, decortication of, in fibrous pericarditis, 157, Bialock-Taussig operation for morbus coeruleus, 238, experimental reconstruction of cardiac valves by venous and pericardial grafts, 240, 4 cases of polypoid tumor (myxoma) within left auricle of, 240, tachycardia in children during anesthesia, 301, experimental study of collateral coronary circulation produced by cardiopneumonepexy, 356, experimental anastomoses of vessels to, 356, aspiration of blood from pericardium in treatment of acute cardiac tamponade after injury, further experience, with report of cases, 450, utility of intravenous procaine in anesthetic management of cardiac disturbances, 510, angiocardiography in congenital disease of, of cyanotic type with pulmonary stenosis or atresia, tetralogy of Fallot and pseudo truncus arteriosus, 513, probable cyst of pericardium with disturbances of cardiac rhythm, 605
- Hemangioma, Primary, of skull, rare cranial tumor, 511
- Hematemesis, 361, massive, 454
- Hematoma, Multilocular, of mammary gland, 232, diagnosis of chronic subdural, in children and adolescents, 406, study of chronic subdural, 539
- Hematuria, Cause of, 272
- Hemophilia, Clinical study of 40 patients, 394
- Hemorrhage, Management of massive gastroduodenal, 162, massive hematemesis, 454, variant of Hofstätter Cullen sign in intra-abdominal, from ectopic pregnancy, 479, delayed, following delivery, puerperal infection of Couvelaire with, 572
- Hemorrhoids, Note on treatment of, after a few accidents following sclerosing injections, 251
- Hemosiderosis of lung due to mitral disease, 603
- Hemostasis, Colonic and proctologic disease, collective review, 105
- Heparin, Effect of caronamide with, on coagulation of human blood, 103, studies on burns, effect of, on circulating blood plasma and proteins in experimental burns, 597
- Hernia, Diaphragmatic, of liver, 205, displacement of esophagus into new diaphragmatic orifice in repair of paraesophageal and esophageal hiatus, 240, strangulated femoral, relationship of contents of hernial sac to clinical manifestations and prognosis, 243, some observations on functional anatomy of inguinal, and its bearing on operative treatment, 360, coexistence of intra-abdominal lesions in patients with epigastric, 372, so-called, of semilunar line of Spiegel, 453, strangulation of diaphragmatic, 453, hiatus, 453, differential diagnosis of hiatus, and coronary artery disease, 453, right retrosternal diaphragmatic, 514, incidence of hiatus, and associated lesions diagnosed with roentgen rays, 551
- Hip, Developmental coxa vara, 192, arthroplasty in cases of congenital dislocation and subluxation of, in children, 194, congenital coxa vara, 285, approach to and exposure of, for mold arthroplasty, 287, treatment of suppurative of, following injuries by firearms, 291, treatment of true congenital dislocations of, 291, management of intracapsular fractures of, 391, lesions of, in infants and children seen at Newington Home and Hospital for Crippled Children, 408, attempts at prosthetic reconstruction of, after resection of femoral head, 497, etiology of congenital dislocation of, 586, morphology of congenital coxa vara, 587, congenital dysplasia of, relationship between congenital subluxation and congenital dislocation, 587, further studies in articular replacement, 588, pinning for slipping of epiphysis of femoral head, 589
- Hirschsprung's disease, Discussion on, 558
- Histology, Statistical studies of role of, in postoperative prognosis of mammary carcinoma, 233
- Hodgkin's disease, Pregnancy and, 264, histopathologic and clinical classification with radiotherapeutic response, 517
- Hormones, Treatment of inoperable carcinoma of breast with, 349, clinical study of 1 methyl bisdehydrodrosynolic acid, new synthetic estrogen, 376, histophysiology of sexual zone of adrenal cortex, 475, value of implantation of hypophyseal tissue in treatment of hypophyseal insufficiency, 519, effects of various estrogenic preparations, changes in vaginal mucosa and general status of climacteric women following injection of aqueous suspensions of estrone and estradiol, 569
- Hospitals, Infection, problem in, 206
- Humerus, Traumatic posterior (retroglenoid) dislocation of with castration in, 375
- Hydatidiform mole, Surgical indication of hysterectomy with castration in, 375
- Hyperemia, Vascular congestion and, 262
- Hypertension, Syndromes of, due to craniocervical malformations, clinical, radiologic, and neurosurgical observations, 34, results of specifically co-ordinated plan of medical and surgical treatment of essential, 35, personal experiences with surgical treatment of essential, 231, results of surgical treatment of unilateral nephropathy in, 271, histological lesions of 32 supra renal capsules removed surgically for permanent arterial, 381, evaluation of treatment of, 440, medical and surgical treatment of, 542, combined splenectomy and portacaval shunts in treatment of portal hypertension, 564
- Hyperthyroidism, Frequency of, causes and therapy, 32
- Hypophysis, Giant adenomas of, considerations on 2 cases, 228, Rathke's cleft and its cysts, 342, fetal cell adenoma of, 343, value of implantation of tissue of, in treatment of insufficiency of, 519, action of extracts of anterior and posterior lobe of, on water metabolism in pregnancy, 575
- Hysterectomy, Surgical indication for, with castration in hydatidiform mole, 375
- ICE water bath, Renal response to thermal stimulus, 85
- Icterus, Serum bilirubin during course of, 172, surgical jaundice, collective review, 209
- Ileum, Occurrence of gas stoppage sensation in acute obstruction of, 168, involvement of, in chronic ulcerative colitis, 249
- Incisions, Costal arch resection, substitute for transthoracic approach to upper abdominal pathology, 47, new, and revised techniques in peripheral surgery, 97
- Incontinence, Of urine caused by dysplasia of vesical neck, with paradoxical vesicoureteral reflux, nephroureterectomy and Young's operation, classification of urinary, 190, operative treatment of female stress, 477

- Infections, Neurological surgery through years of World War II, collective review, 1, bacitracin in ocular, 27, splenectomy in brucella, 63, role of chemotherapy in wounds and surgical, study of significance of gram-negative pathogens in fresh trauma and chronic, 96, penicillin therapy with prolonged interval dosage schedules, 96, re evaluation of penicillin dosage schedules, 96, colonic and proctologic disease, collective review, 105, control of experimental, of anterior chamber and of vitreous by subconjunctival and retrobulbar injections of crystalline penicillin in doses of 1,000,000 units, 143, of cornea due to herpes simplex, experimental study, 144, umbilical healing and, 185, results of systemic administration of antibiotic (bacitracin) in surgical, 200, hospital problem, 206, air, with dust liberated from clothing, 207, plaster of paris as source of, in tetanus and gas gangrene, 207, evaluation of antiseptic drugs and antibiotics in treatment of, of urinary tract, 278, streptomycin in urogenital, 279, bacteriological analysis of plaster bandages, 310, studies in virulence of clostridium welchii, 414, blastomycosis infestation with paracoccidioides brasiliensis, anatomopathologic study and fluorescent coloration of parasite, 414, studies on self-disinfecting power of skin, 414, occurrence of, after pulmonary resection, 449, extra peritoneal cesarean section in patient with, 481, streptomycin in nontuberculous urinary, 494, streptomycin in surgical, nonpulmonary tuberculosis (lymph nodes, urinary tract, bone, and peritoneum), 509, bacitracin in surgical wound, 510, recurrent tetanus, 598, streptomycin in nontuberculous, 599, blastomycosis, special study of Jorge Lobo's variety, 609
- Inflammation, Diffuse, of cartilage, case report of hitherto unreported entity, 87, acute peritonitis, 243
- Intervertebral discs, Certain observations on prolapse of, in lumbosacral assimilation of vertebrae, 285, plain radiography in intraspinal protrusion of lumbar, correlation with operative findings, 511, hernias of, in cervical region, 541
- Intestines, New observations on oral opaque enema of small, 55, intussusception in childhood, 55, anemia following resection of, 56, 2 cases of enterogenous cysts, 63, acute operative complications involving, in connection with pregnancy, 73, appraisal of oral streptomycin as antiseptic for, with observations on rapid development of resistance of *Escherichia coli* to streptomycin, 167, occurrence of gas stoppage sensation in acute obstruction of ileum, 168, surgical aspect of Meckel's diverticulum, 168, results in ureteroin testinal anastomosis, 187, surgical treatment of polyps of large, 247, comparison of efficacy of therapeutic agents in treatment of experimentally induced diffuse peritonitis from, 312, some observations on functional anatomy of inguinal hernia and its bearing on operative treatment, 360, acute perforations of stomach and small bowel ulcerations, 362, obstruction of, indications for surgical treatment, 365, primary malignant disease of small bowel, 366, necrotic jejunitis, 366, internal strangulating obstruction of bowel, collective review, 417, acute obstruction of small bowel, 460, pneumatosis of, roentgen diagnosis and surgical management, 460 malignant tumors of small, 461, diagnosis of congenital obstruction of stomach and small in newborn, 514, regional hypertrophic enteritis at ileocecal bottle neck (Crohn's disease), 552, treatment of jejunal ulcer, follow up study, 553 radiology of small, in aged, 606
- Intocostin, Treatment of tetanus, 97
- Intussusception in childhood, 55
- Iodine, Radioactive, as diagnostic aid for intrathoracic goiter, 102, treatment of thyrotoxicosis, 536
- Ioduron, Visualization of cavum tympani and auditory canal with opaque medium, experiments on dogs, 303
- Iridencleisis, Anterior flap sclerotomy with basal, preliminary note, 26
- Isotopes, Some tracer and therapeutic studies with artificial radioactivity, 101
- JAWS, Internal wire immobilization of fractures of, 428
- Jejunitis, Necrotic, 366, 2 cases of persistent, following partial gastrectomy, 461
- Jejunum, Gastrojejunal ulceration, 51, treatment of ulcer of, comparative follow up study, 553
- Joints, Treatment of compound injuries of, of knee, 88, knee pain of muscular origin, 194, partial patellectomy in fractures of knee, 195, congenital discoid meniscus, 195, changes in, of knee after meniscectomy, 196, study of congenital temporomandibular ankylosis, 223, causation and treatment of painful stiff shoulder, subdeltoid bursitis, periarthritis, tendinitis, and adhesive capsulitis, 282, arthrodesis of wrist by technique of Smith and Petersen, 287, approach to and exposure of hip for mold arthroplasty, 287, treatment of complicated inflammatory processes of elbow articulation, 289, arthrodesis of ankle, 293, surgical treatment of osteoarticular tuberculosis, 387, arthroplasty of knee, 389, arthroplasty of knee, 389, arthrodesis of ankle, in posttraumatic conditions, 389, wounds of extremities, 397, surgery in treatment of chronic arthritis, 496, arthrograms, 515, indications and results of management of tuberculosis of, 586, synovial membrane of knee in pathologic conditions, 588, further studies in articular replacement, 588, arthroplasty of elbow, 589, pinning for slipping of epiphysis of femoral head, 589
- KERATITIS rosacea, Allergic conditions of eye, 24
- Keratosis, Lack of extractable carcinogens in skin of patients with multiple precancerous, of actinic origin, 415
- Kidney, Indications and results of x ray examinations in trauma of, 77, intravenous urography and retrograde pyelography in subcutaneous injuries of, 78, diagnostic and therapeutic considerations of horseshoe, 78, tumors of, 79, injury of vena cava during nephrectomy, 79, response of, to thermal stimulus, 85, urinary tuberculosis, 85, several indications for infiltration of pedicle of, during pregnancy and puerperium, 184, indications for decapsulation of, during pregnant and puerperal state, 184, function of, in fetus, 185, implantation of secondaries from renal carcinoma (hypernephroma) within ureteral lumen, 186, conditions of bladder and ureters after nephrectomy for tuberculosis of, 188, report of Clinical Cancer Research Committee of British Empire Cancer Campaign, 190, double formations of pelvis of, and ureters, embryology, occurrence and clinical significance, 270, case of chyluria of right, 270, pararenal sympathicoblastoma in children under 5 years of age, 271, results of surgical treatment of unilateral nephropathy in hypertension, 271, remaining, in tuberculous cystitis after nephrectomy, 271, evaluation of principles concerned in management of trauma to kidney, 313, instrumental visualization of pelvis of, 382, perirenal abscess, 382, genesis and significance of nephrography, 486, etiological and therapeutic experiences concerning stones in, and ureter, 487, urinary citrate excretion in patients with calculi in, 487, classification of tumors of, 487, branched calculi of, 487, renal and osseous lesions, 578, consideration of paraneuritic tumors, 579, problem of perirenal or capsular tumors of, 581, tumors of renal pelvis, 581, roentgenologic picture of nonspecific pyelitis, 604

- Knee, Treatment of compound injuries of, 88, pain in, of muscular origin, 194, partial patellectomy in fractures of, 195, congenital discord meniscus, 195, changes in, after meniscectomy, 196, question of gangrene following popliteal injury, 297, arthroplasty of, 389, arthroplasty of, 389, synovial membrane of, in pathologic conditions, 588, late results of operative treatment of recurrent dislocation of patella, 591
- Krukenberg tumor, Two cases of, 178
- Kymography, Rotary, at 100 revolutions, 203, new applications of principles of, 303
- L**ABOR, Clinical use of sodium vinylbarbital by intravenous route in obstetrics, 74, modern indications for cesarean section, 181, fetal mortality in breech deliveries, 183, investigations on prolonged pregnancy, 265, internal podalic version and extraction, 265, management of occiput posterior position, 266, cesarean section in Dublin, 266, third stage of, plea for manual removal of placenta, 267, intravenous demerol scopolamine amnesia during, 300, medical treatment of uterine inertia, 377, dystocia in face presentation, 377, dystocia due to obstructing tumors, 377, cesarean section in contaminated cases, résumé of 1,138 observations, 378, obstetrical uterine ruptures in Finland during years 1936 to 1943, from point of preventive and clinical treatment, 378, observations on series of, 480, extraperitoneal cesarean section in profoundly infected patient, 481, 5,000 consecutive deliveries without maternal death, 481, vaginal delivery following cesarean section, 482, report on 159 third degree lacerations, 482, role of massive blood transfusions in management of ruptured uterus and other serious obstetric shock, 483, importance of pelvimetry of inferior strait with attention to two new diameters, sacrospinous and symphysioepiparietal, 484, artificial delivery and morbidity in puerperium, 571, physiopathology of uterine contraction, 573, is Hegar-Sellheim internal pelvic examination unnecessary, 574
- Labyrinth, Test findings before and after fenestration of, 147
- Lacrimal duct, Implant of vitallium tube in treatment of stenosis of, 142
- Larynx, Cancer of, statistical study, 33, roentgen treatment of carcinoma of, by concentration method, 100, cancer of, 147, amyloid tumors of trachea, bronchi, or, report of 15 cases, 538
- Legg-Perthes' disease, Syndrome of many etiologies, presentation of case, 87
- Legs, Etiology of ulcers of, and their treatment by resection of popliteal vein, 92, evaluation of phlebography of normal lower extremity, 99, treatment of varicosities of lower extremities, 296, comminuted and segmental fractures of, 391, investigation and treatment of arterial disturbances in, 393, blood supply of cross pedicle flaps in, 396, comparative study of methods of treatment of diaphyseal fractures of, 592
- Leiomyosarcoma of uterus, 178
- Lempert decompression operation for hydrops of endolymphatic labyrinth in Ménière's disease, 31
- Lens, retrolental fibroplasia, 219
- Leucotomy, Transorbital, 34
- Lightning, Injuries and death from, 504
- Limit plastica and sclerosing carcinoma of stomach (carcinoma disseminatum Krompecher, carcinoma fibrosum Konjetzny, 459
- Lipoma, Benign tumors of stomach, case of submucous ventricular, simulating cancer of stomach, 245, mammary, 349
- Lipoma-angiolipomas, Multiple, 610
- Lips, Cleft, and palate, some technical procedures used in treatment, with reference to closure of complete cleft of anterior half of palate, 435, method of cutting and suturing, 436
- Liver, Strangling diaphragmatic hernia of, 46, thoracoabdominal approach for portacaval anastomosis, 46, serum bilirubin during course of icterus, 172, diaphragmatic hernia of, 205, surgical jaundice, collective review, 209, abscesses of, 44 observations, analysis and statistics, 256, primary cancer of, hepatoma, 256, pseudoscarcinous carcinosis of, 368, structure of, in fatal burns, 520, use of portacaval anastomosis in portal cirrhosis, 560, primary carcinoma of, 25 year study, 561
- Lucite, Evaluation of extrapleural pneumonolysis with plombage with, 543
- Lungs, Arteriovenous fistula of, treated by ligation of pulmonary artery, 39, problem of solitary tumors of, 39, bridging of esophageal defect by pedicled flap of tissue of, 44, decortication of nonexpandable postpneumothorax tuberculous, 155, use of streptomycin in resection for tuberculosis of, 156, use of streptomycin in resections of, 156, diagnosis of stenosis of, by angiocardiology, 203, roentgenologic significance of hamartoma of, 204, thoracoplasty in treatment of giant tuberculous caverns, 235, studies in abscess of, abscess of, and bronchial carcinoma, 235, 90 abscesses of, treated by bronchial aspirations, 236, bronchogenic carcinoma of middle lobe and segmentary bronchitis, 237, covering of lattice, and residual apical pleural cavity by transplantation of tubed pedicle flap, 238, indications for resection of, with special reference to extent of operation, 238, incidents and accidents in bronchoscopy, 241, anesthesia for operations for relief of congenital stenosis of, 242, peripheral vascular disease in, 303, evaluation of lesser circulation as portrayed by roentgenogram, 305, practical correlative anatomy of bronchial tree and, 350, bronchostenosis of inflammatory origin with report of 6 cases, 350, arteriovenous aneurysm of, cured by resection, 350, streptomycin as an adjunct in surgical treatment of tuberculosis of, 352, role of streptomycin in surgery of tuberculosis of, 352, evaluation of streptomycin as protective agent in resection of, for tuberculosis, 353, comparison of results in 200 consecutive resections for tuberculosis of, 353, disposal of bronchial stump in lobectomy and pneumonectomy for bronchiectasis, 353, on abscess of, 353, clinical considerations on case of tumor of upper lobe of right, (Pancoast's syndrome) with secondary infection, diffusion of process to right supraclavicular and laterocervical region and subsequent fistulization, 354, diagnosis of carcinoma of, 354, carcinoma of, with intracranial metastasis, successful removal of metastatic and primary lesions, 354, pulmonary resection for metastatic malignancy, 355, streptomycin in surgical patients, 355, tracheobronchial tuberculosis in general and its connection with pulmonary surgery, 443, analysis of variations of segmental bronchi of right lower lobe of 50 injected, 443, analysis of variations of segmental bronchi of left lower lobe of 50 dissected, and 10 injected, 445, angiocardiology in differential diagnosis of pulmonary neoplasms, 446, adenoma of bronchus, 446, bronchiectasis, its curative treatment by pulmonary resection, 446, primary bronchogenic carcinoma, correlation of recent literature with 131 proved cases, 447, alveolar cell carcinoma of, (pulmonary adenomatosis jag ziekte?), 448, survival in primary carcinoma of, 448, segmental resection of, 449, occurrence of infection after pulmonary resection, 449, study of postoperative

SUBJECT INDEX—ABSTRACTS—VOLUME 89

xv

- atelectasis of, 504, bronchography, 512, surgical extrapleural pneumothorax in treatment of large tuberculous cavities at upper lobe of, 543, experimental and clinical study of collapse therapy with fiberglass wool and fabric, 543, evaluation of extrapleural pneumolysis with lucite plombage, 543, malignant nature of bronchial adenoma, 544, pneumonectomy in case of Besnier Boeck's sarcoidosis, 544, clinical use of prosthesis to prevent overdistention of remaining, following pneumonectomy, 544, pulmonary tuberculosis and pregnancy, 575, hemosiderosis of, due to mitral disease, 603, cavity form of pulmonary neoplasm, 605
- Lymphadenitis, Abdominal, study of 40 observations, 373
- Lymphangioma, Retroperitoneal, with fistula in colon demonstrated by roentgenography, 259
- Lymph nodes, Adenocarcinoma of axillary, without demonstrable breast lesion, 233
- Lymphogranuloma venereum, Rectal stricture of, 57, selection of operative procedure for patients with, of rectum, 463
- Lymphosarcoma of gastrointestinal tract, with a report of 21 cases, 361
- Lymph system, Congenital elephantiasis, 293, notes on anatomy and physiology of thoracic duct and on treatment of injuries to it, 297, Hodgkin's disease, histopathologic and clinical classification with radiotherapeutic response, 517
- M**ALARIA, Value of splenectomy in splenomegalies caused by, 564
- Malignancy, Of uterine fundus subsequent to irradiation for benign pelvic conditions, 260, immediate and late results of intracavitary radium therapy for lesions of cervix, 309, ligation of carotid arteries for advanced, static, 355, primary disease of small bowel, 366, cancer problem, 415, doubtful changes of, in endometrial epithelium, report on 60 cases from Radiumhemmet, 469, 4 new cases of neoplasm on cervical stump, 525, ovarian tumors in pregnancy, collective review, 532, disease of face and scalp, excision and repair, 532, diagnosis of, of nasopharynx, cytologic studies by smear technique, 536, in cryptorchidism, 584, in infancy and childhood, 610
- Mastectomy, Radical, 234
- Mastitis, Plasma cell, 232
- Mastoidectomy, Surgery of chronically discharging ear, 337, modified radical, preservation of cholesteatoma matrix, method of making flap in endaural technique, 338
- Mastoidotomy, Lempert endaural subcortical, for cure of chronic persistent suppurative otitis media, 337
- Maxilla, Epithelial tumors associated with developmental cysts of, 141, benign cysts of superior, with reference to cyst of maxillary sinus, clinicopathologic study of 30 cases, 435
- Mecholyl, Production of gastric and duodenal ulcers by prolonged administration of, 363
- Meckel's diverticulum, Surgical aspect of, 168
- Mediastinitis, Treatment of, from perforation of esophagus, 358
- Mediastinum, Gastric cyst of, 158, case of thymolipoma, 350, statistical contribution to surgery of, 451
- Medulloblastoma, Nonoperative management with roentgen therapy after aspiration biopsy, 605
- Megacolon, Myenteric plexus in congenital, study of 11 cases, 367
- Megaloureter, Report of 2 cases, 186
- Melanoeptithelioma of anus and rectum, 254
- Melanoma, Prognosis in uveal, 28
- Ménieres disease, Lempert decompression operation for hydrops of endolymphatic labyrinth in, 31
- Ménieres syndrome, Relation to chemistry, etiologic study, 336, observations on vitamin deficiency as causative factor, vestibular disturbance, 336
- Meninges, Frontonasal encephalomeningocele corrected by plastic procedure on, and bone, 228
- Meningiomas, Analysis of electroencephalographic findings in 40 cases of varied brain tumor, electroencephalographic findings in, 540
- Meningitis, Facial injuries followed by, with recovery, 32
- Meniscus, Congenital discoid, 195
- Menopause, Significance of abnormal vaginal smears in, 263
- Menstruation, Newer concepts of, 67
- Mesentery, Revascularization following experimental vascular occlusion in, 551
- Metabolism, Potassium, in connection with operations, 503, studies on protein depleted patients receiving large part of their nitrogen intake from human serum albumin administered intravenously, 519, action of folliculin and progesterone on water, in pregnancy, 574, action of extracts of anterior and posterior hypophysis on water, in pregnancy, 575
- Metacarpals, Treatment of fractures of, 290, transfer of, 388
- Metaplasia, Three cases of osseous, of cytogenous stratum of endometrium, remarks on pathogenesis, 380
- Metastases, Researches on microscopic, of supraclavicular lymph nodes in breast carcinoma, 349, carcinoma of lung with intracranial, successful removal of metastatic and primary lesions, 354, pulmonary resection for, from malignancy, 355, right inguinal and iliac sarcomatoid myxoma from previous remote epididymal blastic phase, 494
- Methyl bisdehydrodisynolic acid, Clinical study of, new synthetic estrogen, 376
- Micturition, Neurological surgery through years of World War II, collective review, 1
- Migraine, Allergic conditions of eye, 25
- Mitral valves, Surgical treatment of stenosis of, valvuloplasty, 41
- Mongolism, Eyes in, 216
- Mortality, Maternal, analysis of 10 year period from 1937 through 1946 at Cincinnati General Hospital, 269
- Mouth, Penicillin therapy in oral surgery, 223, cleft lip and palate, some technical procedures used in its treatment, with reference to closure of complete cleft of anterior half of palate, 435, method of cutting and suturing lip, 436
- Muscles, Operative treatment of vertical tropias, 142, motor block of extraocular, by deep orbital injections, 217, ischemic necrosis of anterior tibial, 286, myanesin as relaxant for, 300, ruptures of, and tendons, 496, substitution of gluteus maximus, new operative technique, 498
- Myanesin, As muscle relaxant, 300
- Myasthenia gravis, Comparison of thymic hyperplasia in, and exophthalmic goiter, 358, thymectomy in treatment of, report based on 32 cases, 550
- Mycosis, Infection of eye, 217
- Mydriasis test, Provocative, in glaucoma, 29
- Myeloma, Recent studies of multiple, sternal and rib puncture and results of treatment with sulbamidine, 284
- Myxoma, Four cases of polypoid tumor, within left auricle of heart, 240, right inguinal and iliac sarcomatoid, metastasized from previous remote epididymal blastic phase, 494

INTERNATIONAL ABSTRACTS OF SURGERY

- AVI
- N**ARES, Physiologic surgery of, 222
 Nasopharynx, Potential hazards from radiation treatment of hypertrophied lymphoid tissue in nasopharynx, 339, diagnosis of malignancy of, cytologic studies by smear technique, 536
 Neck, Clinical aspects of chronic thyroiditis, 32, open wounds of brachial plexus, 440, spasmodic torticollis, surgical treatment, 496, treatment of thyrotoxicosis, 536, intervertebral disc hernias of cervical region, 541
 Necrosis, of intraocular tissue, 218
 Nephrectomy, Injury of vena cava during, 79
 Nephrography, Genesis and significance of, 486
 Nerves, Neurological surgery through years of World War II, collective review, 1, physiological aspects of vagotomy, 53, hypergenesis of cholecystitis due to condensation of, 58, neuromuscular dysfunction of urinary tract, 85, glossopharyngeal neuralgia, 151, peripheral sensory innervation of digestive tract, 161, effects of streptomycin on system of eighth, 208, electrodiagnosis of lesions of peripheral, in man, 230, painful sequelae of injuries to peripheral, 230, experimental and anatomosurgical study of anastomosis of phrenic and recurrent, for treatment of traumatic lesions of inferior laryngeal, 231, x ray observations before and after vagotomy, 305, tumors of optic, long survival in 3 cases of intracranial tumor, 336, trigeminal tractotomy, observations on 48 cases, 344, tumors of acoustic, clinicosurgical considerations of 250 cases, 344, surgical routes in high lesions of sciatic, 347, subarachnoid spaces of root sheaths in lumbar region, 408, vasomotor changes in injuries of peripheral, 439, modern history of surgery of peripheral, 440, late paralysis of ulnar, and occupational accident, 541, traumatic lesions of sciatic, and its branches, 541, causalgic syndromes, 541
 Nervous system, Neurological surgery through years of World War II, collective review, 1, hypertensive syndromes due to craniovertebral malformations, clinical, radiologic, and neurosurgical observations, 34, role of, as cause of immediate general symptoms following burns, 609, congenital dermal sinuses, 609
 Neuralgia, Glossopharyngeal, 151, glossopharyngeal, extracranial neurectomy, 228
 Neurinoma in gastrointestinal tract, 455
 Neuroblastoma, Proptosis due to, of adrenal cortex (Hutchinson's syndrome), report of case, 24
 Neurofibroma, 246
 Neurofibromatosis, Roentgenologic features of, 406, contribution to recognition of severe complications of gastrointestinal, 456
 Neuroma, Postoperative biliary dyskinesia due to, of cystic duct, 60
 Neurosurgery, Anesthesia for, 299, preoperative and postoperative care in, 347, anesthesia for, analysis of, 1,000 cases, 405
 Nevi, Common nonvascular, and their treatment, 413
 Newborn, Chondrodystrophy fetalis, 74, hemolytic disease of, 267, abortions, premature births, and weight of, born during war period, 379, use of replacement transfusion in diseases other than hemolytic disease of, 502, diagnosis of congenital obstruction of stomach and small intestine in, 514, clinical and roentgen manifestations of erythroblastosis fetalis, 516, penicillin as prophylactic against ophthalmia neonatorum, comprehensive study, 532
 Nose, Tuberculosis of ear, nose, and, treated with streptomycin, report of 12 cases, 222, physiologic surgery of nares, 222, role of septum in rhinoplasty, 339, antibiotics in treatment of diseases of ear, throat and, 534
 Nucleus pulposus, Neurological surgery through years of World War II, collective review, 1, hypobaric pontocaine spinal anesthesia for exploration for extruded, 201
 Nutrition, Parenteral use of water, dextrose, electrolytes, fat, and vitamins, 94, parenteral feeding of protein, 103
- O**BSTETRICS, Maternal mortality, an analysis of 10 year period from 1937 through 1946 at the Cincinnati General Hospital, 269, radiodiagnosis in gynecological analgesia in, 601
 Operation, Biological significance of protein concentration and changes occurring in gynecologic laparotomies, 68, new incisions and revised techniques in peripheral surgery, 97, use as controls of various hematologic values and in particular plasma protein level after, 298, blood determination and estimation of blood loss during surgical, 301, preoperative and postoperative care in neurosurgery, 347, potassium metabolism in connection with, 503, observations on behavior of chlorides, glucose, and proteins in blister fluids with regard to surgical interventions, 503, study of pulmonary atelectasis after, 504, major surgical, in presence of bundle branch block, 597
 Orbit, Fascia of, 141, fractures of orbital floor, 217
 Orthopedics, Quantitative parathyroidectomy in, 293
 Osteitis fibrosa disseminata, 495
 Osteoma, osteoid, 282
 Osteomyelitis, Early diagnosis of acute septic, periostitis and arthritis, and its importance in treatment, 407
 Osteosynthesis, Metallic, with medullary graft for pseudarthrosis of tibia, 498
 Otitis media, Lempert endaural subcortical mastoidotomy in panectomy for cure of chronic persistent suppurative, 337
 Otosclerosis, Histopathologic investigations on localization, number, activity, and extent of foci of, 432, acoustic function before and after operations for, 433, Popper's operation for, 433, vestibular function prior to and following operation for, 535, biochemical conditions in patients with, 535, conditions of external auditory meatus and tympanic membrane in patients with, 535
 Ovaries, Significance of cystic enlargement of, with respect to treatment, 65, report of 2 cases of tumor of internal theca of, 65, dysgerminoma of, 66, concerning 2 cases of Krukenberg tumor, 178, gynecoblastoma of, 261, limitation and extension of syndrome of Demons Meigs, 472, tumors of, in pregnancy, collective review, 525
 Oxygen, Certain factors influencing percentage of, in mixtures of nitrous oxide and, 97
- P**ACHYMENINGITIS, Purulent, 149
 Pain, Neurological surgery through years of World War II, collective review, 1, in knee of muscular origin, 194, causalgic syndromes, 541
 Palate, Hard and palatine fissure, 222, cleft lip and, some technical procedures used in its treatment, with reference to closure of complete cleft of anterior half of, 435
 Pancreas, Operative diagnosis of indurations of duodenum and, 61, carcinoma of, 371, cystic fibrosis of, 466, on acute affections of, following gastric resections for ulcer or cancer, and possibilities of avoiding them, 562
 Pancreatectomy, Indications and results of left, report of 16 cases, 467
 Pancreatitis, Traumatic rupture of choledochus associated with acute hemorrhagic, and bile peritonitis, 60, re-

SUBJECT INDEX—ABSTRACTS—VOLUME 89

xvii

- current acute, observations on etiology and surgical treatment, 61, chronic recurrent, clinical and laboratory aspects, serial serum diastase levels following prostigmine stimulation, 370, surgical treatment of, 466
- Pancreatolithiasis, 62
- Paralysis, The reverse King operation, surgical procedure for restoration of phonation in cases of aphonia due to unilateral vocal cord, 341, late spinal, after avulsion of brachial plexus, 346, treatment of residual, brachial plexus injuries, 346, cause of spinal, with special attention to factors responsible for compression, 439, substitution of musculus gluteus maximus, new operative technique, 498, operative restoration following facial, 540, late, of ulnar nerve and occupational accident, 541, tendon transfers and arthrodeses in combined median and ulnar nerve, 589
- Paraplegia, Pressure sores in patients with, 599
- Parathyroidectomy, Quantitative, in orthopedics, 293
- Parenteral feeding of protein, 103
- Parenteral therapy with water, dextrose, electrolytes, fat, and vitamins, 94
- Parotid gland, Chemosurgical treatment of tumors of, 339
- Patella, Late results of operative treatment of recurrent dislocation of, 591
- Patella cubiti, New method of treatment for its avulsion, 193
- Pectus excavatum, Operative treatment of, 442
- Pediatrics, Malignant disease in infancy and childhood, 610
- Pelvimetry, Importance of, of inferior strait with special attention to two new diameters, sacrobiparietal and symphyseobiparietal, 484
- Pelvis, Observations on delay period in diagnosis of cancer of, 68, malignant tumors of uterine fundus subsequent to irradiation for benign conditions of, 260, roentgenologic study of viscera in, in pregnant woman, 379, vascular congestion and hyperemia, etiology and therapy, 474, vascular congestion and hyperemia, clinical aspects of congestion fibrosis syndrome, 474, is the Hegar-Sellheim internal examination of, unnecessary, 574
- Penicillin, Therapy with prolonged interval dosage schedules, 96, re-evaluation of dosage schedules for, 96, anthrax, 36 human cases of external type treated successfully with, 97, intravitreal injections of, study on levels of concentration reached and therapeutic efficacy, 142, control of experimental infections of anterior chamber and of vitreous by subconjunctival and retrolbular injections of crystalline in doses of 1,000,000 units, 143, distribution of, in eye after injections of intramuscular routes, 143, controversial points in therapy with, of ocular diseases, 143, preliminary note on treatment of hypopyon ulcer with crystalline, in adrenalin in doses exceeding 50,000 units injected by subconjunctival or retrolbular routes, 145, therapy in oral surgery, 223, use of, in open injuries of hand and fingers, 299, as prophylactic against ophthalmia neonatorum, comprehensive study 532, experiences with, in treatment of acute otitis media, 534, abscess of brain due to Clostridium perfringens treated with, 539 massive therapy of abdominal actinomycosis with, 566, study of vehicles and adjuvants for sulfonamides and, 599
- Penis, Gangrene of, 273, treatment of cancer of, 278
- Pentothal sodium, Study of anesthesia with, and critical investigation of use of succinate as an antidote 301
- Pericarditis, Chronic constrictive, study of 53 cases, 41, constrictive, with obstruction of pulmonary veins, 42, decortication of heart in fibrous, 157
- Pericardium, Aspiration of blood from, in treatment of acute cardiac tamponade after injury, further experience, with report of cases, 450, probable cyst of, with disturbance of cardiac rhythm, 605
- Peripheral nerves, Neurological surgery through years of World War II, collective review, 1, clinical assessment of injuries of, 35, electrodiagnosis of lesions of, in man, 230, painful sequelae of injuries to, 230, cervical plexus injuries, 345, resection of clavicle in lesions of cervical plexus, 345, traction injuries of brachial plexus in adults, 346, operative approach to supraclavicular plexus injuries, 347, wounds of extremities, 397, vasomotor changes in injuries of, 439, modern history of surgery of, 440
- Peritonitis, Treatment of acute, 243, biliary, 255, comparison of efficacy of therapeutic agents in treatment of experimentally induced diffuse, of intestinal origin, 312, benign paroxysmal, second series, 360, mechanism of shock in, 454
- Phagedenism, Tropical ulcer, problem of, 311
- Pharynx, Prognostic criteria and therapeutic suggestion for treatment of tumors of, 224, clinical and pathologic study of tonsil tags, 437
- Pheochromocytoma, 486
- Phlebography, Evaluation of, of normal lower extremity, 99
- Physiopathology, Symposium, corneal transplantation, 26
- Pilonidal disease, Colonic and proctologic disease, collective review, 105
- Placenta, Facts pertinent to rational concept of premature detachment of, 264, third stage of labor, plea for manual removal of, 267, remarks on total and prolonged retention of, in abortion, 380
- Placenta previa, Conservative treatment of, 264
- Plasma, Dextran as substitute for, 310, dextran as substitute for, 310, volume of, and extravascular fluid volume during pregnancy and puerperium, 482
- Plaster, Bacteriological analysis of bandages of, 310, sterilization of bandages of, 310
- Plaster of paris as source of infection in tetanus and gas gangrene, 207
- Plastic surgery, Reconstruction following irradiation in injuries, 94, simple method of estimating blood flow with reference to circulation in pedicled skin flaps and tubes, 98, studies in cellular growth, 104, frontonasal encephalomeningocele corrected by meningeal and bony, 228, covering of lattice lung and residual apical pleural cavity by transplantation of tubed pedicle flap, 238, experimental reconstruction of cardiac valves by venous and pericardial grafts, 240, concept and new techniques of dermoepidermal graft, 302, complications and sequelae of untreated fractures of facial bones and their treatment, 335, reconstruction of auricle with diced cartilage grafts in vitallium ear mold, 338, role of septus in rhinoplasty, 339, blood supply of cross leg pedicled flaps, 396, internal wire immobilization of jaw fractures, 428, prefabricated autogenous ear cartilages, 430, method of cutting and suturing lip, 436, mammaryplasty for pendulous breasts, 442, pedicle graft cutaneous ureterostomy, 489, management of severe burns, 505, pressure sores in paraplegic patients, 509, malignant disease of face and scalp, excision and repair, 532, use of fluorescein in estimating blood flow in pedicled skin flaps and tubes, 602
- Pleura, Exploratory thoracotomy in management of empyema, 242, experimental and clinical studies of role of streptomycin in cavity of, 355
- Plexus Injuries of cervical, 345, traction injuries of brachial, in adults, 346, late spinal paralysis after avulsion of brachial, 346, treatment of residual paralysis, in-

INTERNATIONAL ABSTRACTS OF SURGERY

- injuries of brachial, 346, operative approach to injuries of supraclavicular, 347, menteric, in congenital megacolon, study of 11 cases, 367
 Pneumomediastinum, Spontaneous, in pregnancy, 480
 Poisons, Roentgenologic symptoms of esophageal and gastric injuries resulting from caustic, 303
 Poliomyelitis, Scoliosis due to, 497
 Polyposis, Anastomosis of ileum to lower part of rectum and anus, report on experiences with ileorectostomy and ileoproctostomy with reference to, 56, of terminal portion of colon, 462
 Polyps, Gastric, 52, surgical treatment of, of large intestine, 247, lesions of colon and rectum, 251
 Polythene, Experimental production of gradual occlusion of large arteries with, and tantalum, 500
 Popper's operation for otosclerosis, 433
 Potassium, Metabolism of, in connection with operations, 503
 Pregnancy, Ultimate resort in diagnosis of, 71, 2 cases of, in uterus subseptus uniporeus and 1 in double uterus, 71, extrauterine, exteriorized through persistent Malpighi Gartner canal with expulsion of skeletal remnants of embryo, 72, high occipital position, 72, diethylstilbestrol in prevention and treatment of complications of, 73, acute operative intestinal complications in connection with, 73, classification and etiology of functional and organic disturbances of (gestoses), 74, volvulus of sigmoid colon in course of, of 7 months, 180, purpura hemorrhagica as complication of, 180, corpus luteum excision and its effect on production of progesterone, 180, diagnosis of sagittal suture, chin, and ear in posterior occiput to brow presentations, 181, several indications for infiltration of renal pedicle during, and puerperium, 184, indications for renal decapsulation during, and puerperal state, 184, influence of, on cancer of breast, 234, conservative treatment of placenta previa, 264, and Hodgkin's disease, 264, complicated by diabetes mellitus, 264, investigations on prolonged, 265, cough fracture in late, 290, roentgenologic study of pelvic viscera in, 379, ectopic, with reference to abdominal, 478, cervical, 478, operation for severe varicose veins during, 479, anemia of, treated with molybdenum iron complex, 479, certain aspects of eclampsia, 479, capillary fragility and use of rutin in toxemias of, 479, variant of Hofstaetter-Cullen sign in intra abdominal hemorrhage from ectopic, 479, spontaneous pneumomediastinum in, 480, plasma volume and extravascular fluid volume during, and puerperium, 482, danger of dicumarol treatment in, 483, target and resistant red cells in, posthemorrhagic anemias, and blood of umbilical vein, 483, specific blood of fetuses in various months of intrauterine development, 484, review of 445 cases of, complicated by fibromyomas, 485, ovarian tumors in, collective review, 525, diagnosis of tubal, 571, diabetes insipidus and, 571, action of folliculin and progesterone on water metabolism in, 574, action of extracts of anterior and posterior hypophysis on water metabolism in, 575, contribution to study of reports of pulmonary tuberculosis and, 575
 Presentations, High occipital position, 72, management of occiput posterior, 266
 Pressor test, Proximate, in glaucoma, 29, for glaucoma, 30
 Procaine Therapeutic uses of, given intravenously, 405, utility of intravenous, in anesthetic management of cardiac disturbances 510 pharmacologic actions of, given intravenously as analgesic agent, 599, intravenous therapy with, 600
 Progesterone, Corpus luteum excision during pregnancy and its effect on production of, 180, action of folliculin and on water metabolism in pregnancy, 574
 Prolapse, Surgical treatment of genital, 262
 Promin, Studies in experimental ocular tuberculosis, effect of, and promizole on experimental ocular tuberculosis in immune allergic rabbit, 27, studies in experimental ocular tuberculosis, effect of, and promizole in experimental ocular tuberculosis in normal rabbit, 217
 Promizole, Studies in experimental ocular tuberculosis, effect of promin and, on experimental ocular tuberculosis in immune allergic rabbit, 27, studies in experimental ocular tuberculosis, effect of promin and, in experimental ocular tuberculosis in normal rabbit, 217
 Prostatectomy, Occlusion of vesical orifice after suprapubic, 272, perineal, today, 275, retropubic, 276, 65 cases of, according to Freyer's method, 277, radical perineal, 492, retropubic, 583
 Prostate gland, Blood loss in open surgery of, 83, cancer of, and its hormonal management, 189, carcinoma cells in secretions of, 274, cystectomy in male, significance of combined prostatectomy and vesiculectomy with reference to sexual function, 384, extirpation of granulomatous, 492, on roentgen aspect of atrophy of, 604
 Prosthesis, Clinical use of, to prevent overdistention of remaining lung following pneumonectomy, 544
 Prostigmine, Chronic recurrent pancreatitis, serial serum diastase levels following stimulation with, 370
 Protein, Biological significance of concentration of, and changes occurring in gynecologic laparotomies, 68, parenteral feeding of, 103, surgical jaundice, collective review, 209, use as controls of various hematologic values and in particular plasma level of, after surgical intervention, 298, nature of shift of plasma, to extravascular space following thermal trauma, 298, observations on behavior of chlorides, glucose and, in blister fluids with regard to surgical interventions, 503, metabolic studies on patients receiving large part of their nitrogen intake from human serum albumin administered intravenously, 519
 Prothrombin, Critique of methods for its determination and their clinical significance, 501
 Pseudarthrosis, General conceptions of, statistical considerations, 89, delayed autogenous bone graft in treatment of congenital, 387, results of intertrochanteric osteotomy in, of femoral neck, 388, metallic osteosynthesis with medullary graft for, of tibia, 498, clinic and pathologic anatomy of fracture, pseudarthrosis, and malacia of navicular bone, 499, importance of intra medullary nailing for treatment of, 591
 Puerperium, Several indications for infiltration of renal pedicle during pregnancy and, 184, indications for renal decapsulation during pregnant state and, 184, chronic appendicitis in, 267, plasma volume and extravascular fluid volume during pregnancy and, 482, artificial delivery and morbidity in, 571, delayed hemorrhage following delivery, hemorrhagic type of infection of Couvelaire in, 572, scarlatina in, 573
 Pulse, On symptoms of, in central retinal artery, 146
 Purpura, Hemorrhagic, as complication of pregnancy, 180, role of splenectomy in thrombopenic, 372
 Pylorus, Hypertrophy of, in adult, with massive eosinophil infiltration and giant cell reaction, 244
 Pyruvic acid, Elimination of eschar of burns with, 508
 RADIATION, Hematological effects of ionizing, 518
 Radioactivity, Some tracer and therapeutic studies with artificial 101, rate of flow of venous blood in legs, measured with sodium with, 198

SUBJECT INDEX—ABSTRACTS—VOLUME 89

Radium, Irradiation in cancer of tongue, 100, extravascular therapy in cancer of bladder with, 189, immediate and late results of intracavitary therapy with, for malignant lesions of cervix, 309, carcinoma of cervical stump, 309, potential hazards from radiation treatment of hypertrophied lymphoid tissue in nasopharynx, 339, probable trends in irradiation treatment of carcinoma of cervix uteri with improved expanding type of applicator of, 411, reactions to x ray therapy and, in treatment of cancer of uterine cervix, 607, therapy in carcinoma of female urethra, 608

Radon, Study of results obtained in treatment of fractures of lower end of, in insured persons in Finland, 194

Radon, Retinoblastoma (retinal glioma) cured by radon seeds, report of case, 221

Rathke's cleft and its cysts, 342

Raynaud's disease, Observations on, report of 35 cases, 594

Recklinghausen's disease, Roentgenologic features of neurofibromatosis, 406

Rectum, Anastomosis of ileum to lower part of, and anus, report on experiences with ileorectostomy and ileoproctostomy, with reference to polyposis, 56, evaluation of conservative resection with end to end anastomosis for carcinoma of, and lower sigmoid colon, 56, stricture of, due to lymphogranuloma venereum, 57, streptomycin and surgery in anorectal tuberculosis, 58, colonic and proctologic disease, collective review, 105, malignant tumors of colon and, 170, selection of patients and anastomotic procedures for carcinoma of, and rectosigmoid, 171, note on treatment of hemorrhoids after few accidents following sclerosing injections, 251, polypoid lesions of colon and, 251, importance of level of lesion in prognosis and treatment of carcinoma of, and low sigmoid colon, 252, discussion on sphincter excision of carcinoma of, with conservation of colon, 253, surgical treatment of cancer of, and colon, 254, melanoeipithelioma of anus and, 263, tumors of mucosa of, in cancer of uterine cervix, 263, fistula between, and urinary tract, 280, wounds of, critical analysis of current methods of surgical treatment with emphasis on details of operative procedure for patients with lymphogranuloma venereum of, 463, operative treatment of carcinoma of, with reference to preservation of sphincter mechanism, 560

Reflexes, Neurological surgery through years of World War II, collective review, 1

Refrigeration, Tissue-culture evaluation of viability of blood vessels stored by, 394

Respiration, Tetanus treated as problem of, 598

Retina, Fundus dystrophy with unusual features (late onset and dominant inheritance of central lesion of, showing edema, hemorrhage, and exudates developing into generalized choroidal atrophy with massive pigment proliferation), 217, subretinal drainage in detachment of, 220, surgical treatment of detachment of, 220, use of roentgen therapy for diseases of, characterized by new formed blood vessels (Eale's disease, retinitis proliferans), preliminary report, 221, successful diathermy treatment of recurring hemorrhage of, and proliferation of, report of case, 429

Retinoblastoma, (glioma) cured by radon seeds, report of case, 221, treatment of bilateral, 221, diagnosis of, 429

Rh factor in blood groups and their clinical effects, 394

Ribs, Recent studies of multiple myeloma, puncture of sternum and, and results of, 201

Roentgenography, Traumatic bronchial rupture with occlusion, 30, reflux into Wirsung's canal in course of

cholangiography, dystonia of Wirsung's canal, 60, radiologic diagnosis of uterine cancer, 65, studies on backflow in excretion urography, 76, indications and results of, in trauma of kidney, 77, intravenous urography of kidney, 78, Legg-Perthes' disease, syndrome of many etiologies, 87, evaluation of phlebography of normal lower extremity, 99, possibility of venous embolism in course of hysterossalpingography, 99, spindle cell tumors of gastrointestinal tract, 101, gastric cysts of mediastinum, 158, technical conditions of manometric and radiologic control in course of interventions on biliary passages, 173, rotary lymphography at 100 revolutions, 203, diagnosis of pulmonary stenosis by angiocardiography, 203, significance of hamartoma of lung, 204, deformities of pyloric portion of stomach with absence of surgical and pathologic findings, 204, diaphragmatic hernia of liver, 205, multiple osteogenic sarcoma, 205, prognostic criteria and therapeutic suggestions for treatment of tumors of pharynx, 221, surgical treatment of esophageal perforations, 241, retroperitoneal lymphangioma with fistula in colon demonstrated by, 259, in uterine malformation with respect to function, 260, device for obstructing urinary flow in intravenous urography, 270, case report of bilateral cystic lesion of clavicle with evidence of typical cysts, 284, changes in nailed slipped capital femoral epiphysis, 291, new applications of principles of lymphography, 303, visualization of cavum tympani and auditory canal with opaque medium, experiments on dogs, 303, peripheral vascular disease in lungs, 303, stratigraphy in 1947 and in 1930 from initiation to termination of thoracoplasty, 303, symptoms of esophageal and gastric injuries resulting from caustic poisons, 303, gastric dyskinesia, kymographic semeiology, 304, analysis of findings of, in 405 cases of benign gastric and pyloric ulcer, 304, observations before and after vagotomy, 305, diagnosis of lesser or tuberculosis in male by, 305, evaluation of harmful effects of thorotrast on tissues, 306, concerning thorotrast injuries and sarcoma peril of angiographic purposes continue to use thorotrast for angiographic management, 307, evaluation of principles concerned in management of trauma to kidney, 313, thorotrast pyograms in cerebral abscess, 342, retained food remnants in esophageal diverticula resembling tumor and dysphagia, cases of small esophageal diverticula at bifurcation level, 357, of pelvic viscera in pregnant women, 357, radiodiagnosis in gynecology and obstetrics, 357, note, 380, diagnosis of chronic subdural hematoma in children and adolescents, 406, features of retinoblastoma, 406, detection of gastric carcinoma by fluorographic methods, introduction, 406, design, 407, early diagnosis of acute epiglottitis, peritonsillitis, and arthritis, and its treatment, 407, polyostotic fibrous dysplasia (bright's syndrome) and its complications, 407, findings and, 408, subarachnoid space in lumbar region, 408, hip dislocation in children seen at Newington Hospital, 408, pleural Children, 408, sickle cell anemia, 409, changes in sickle cell anemia, 417, vascularization of human testis, 417, tosis intestinalis, and surgical treatment of, in prevention and in diagnosis, 417, syndromes in cholecystitis, 417, rare cranial tumor, 417

- spinal protrusion of lumbar intervertebral discs, correlation with operative findings, 511, bronchography, 512, right retrosternal diaphragmatic hernia, 514, diagnosis of congenital obstruction of stomach and small intestine in newborn, 514, bone sarcomas, 515, clinical manifestations and, of erythroblastosis fetalis, 516, interstitial calcinosis, 516, case of carcinosarcoma of esophagus, 549, incidence of hiatus hernia and associated lesions diagnosed by, 551, uterine, with respect to function, with exclusion of malformations, 567, hemosiderosis of lung due to mitral disease, 603, accuracy of diagnosis of benign gastric ulcer with, 603, of abdominal aorta in individuals over 50 years of age as aid to differential diagnosis between benign and malignant ulceration of stomach, 603, of nonspecific pyelitis, 604, of prostatic atrophy, 604, recent advantages in diagnosis of pathologic conditions of spine, 605, arteriography of collaterals between internal and external carotid arteries, 605, cavity form of lung neoplasm, 605, probable cyst of pericardium with disturbances of cardiac rhythm, 605, of small intestine in old age, 606
- Roentgen rays, Reconstruction following injuries due to, 94, observations on disorders of thyroid gland associated with exposure of suprarenal glands to, 225, irradiation of spleen, 376, hematological effects of ionizing radiations, 518
- Roentgen therapy, Carcinoma of breast, 37, surgical and radiation treatment of cancer of breast, 38, relation of transitional cell buds, Golgi apparatus, and mitochondria to carcinoma of bladder, 82, irradiation in cancer of tongue, 100, of carcinoma of larynx by concentration method, 100, carcinoma of breast, discussion on carcinoma of breast, 153, carcinoma of breast, value of simple mastectomy and, in treatment of cancer of breast, 153, use of, for retinal diseases characterized by new-formed blood vessels (Eale's disease, retinitis proliferans), preliminary report, 221, value of postoperative, of cancer of uterus, 261, role of, in management of carcinoma of breast, 307, intravaginal, in cancer of cervix uteri, 308, review of 10 years' experience with transvaginal, 308, place of deep external, in treatment of carcinoma of cervix by long element needles, 411, lethal dose of total body, in swine, 412, Hodgkin's disease, histopathologic and clinical classification with radiotherapeutic response, 517, carcinoma of cervix, 1948 survey of treatment in United States and Canada, collective review, 521, medulloblastoma nonoperative management with, after aspiration biopsy, 607, reactions to, and radium in cancer of uterine cervix, 607
- Rutin, Capillaries and, in toxemias of pregnancy, 479
- SACRUM**, Giant cell tumor of, case report, 192
- Salivary glands, Tumor of Kuttner, 436
- Sarcoidosis, Pneumonectomy in case of Besnier Boeck's, 544
- Sarcoma, Colonic and proctologic disease, collective review, 105, multiple osteogenic, 205, concerning thorotrast injuries and peril of, from thorotrast, 306, bone, 515, case of carcinosarcoma of esophagus, 549
- Scalp, Malignancy of face and, excision and repair, 532
- Scarlatina, Puerperal, 573
- Sciatic nerve, Surgical routes in high lesions of, 347, traumatic lesions of, and its branches, 541
- Sclera, Scleromalacia perforans, report of case, 219
- Sclerosis, Tuberosus, with cerebral neoplasm, 343
- Scoliosis, Poliomyelitic, 497
- Scrotum, Epithelioma of, 278
- Seminoma, Testicular tumors, and teratoma, 84
- Shock, Traumatic, and curare, 206, mechanism of, in peritonitis, 454, role of massive blood transfusions in management of ruptured uterus and other serious obstetric, 483, management of severe burns, 505
- Shoulder, Experiences and results of various operations for habitual dislocation of, 89, causation and treatment of painful, stiff, subdeltoid bursitis, peri-arthritis, tendinitis, and adhesive capsulitis, 282, acute anterior dislocation of, 288, treatment of recent dislocations and fracture-dislocations of, 288
- Sigmoid colon, Selection of patients and anastomotic procedures for carcinoma of rectum and rectosigmoid, 171, volvulus of, in course of pregnancy of 7 months, 180, importance of level of lesion in prognosis and treatment of carcinoma of rectum and low, 252, complete excision of pelvic viscera in male for advanced carcinoma of, invading urinary bladder, 463, volvulus of loop of, 559
- Sinus, Benign cysts of superior maxilla with reference to cyst of maxillary, clinicopathologic study of 30 cases, 435, carcinoma of antrum, report of 9 cases, with 10 year survey of literature, 535, congenital dermal, 609
- Skin, Rapid disinfection of clean unwashed, 200, chronic progressive infectious gangrene of, 208, common non vascular nevus and their treatment, 413, studies on self disinfecting power of, 414, lack of extractable carcinogens in, of patients with multiple precancerous keratoses of actinic origin, 415
- Skull, Neurological surgery through years of World War II, collective review, 1, late complications following cranioplasty with alloplastic plates, 150, primary hemangioma of, rare cranial tumor, 511
- Smears, Significance of abnormal menopausal vaginal, 263
- Smith-Petersen nail, Intracapsular fractures of neck of femur, follow-up report of 130 patients treated by internal fixation with, 88
- Sodium vinbarbital, Clinical use of, by intravenous route in obstetrics, 74
- Spermatic cord, Varicocele, technique of operation of Eurico Branco Ribeiro, 277, varicocele, 583
- Sphincter, Treatment of carcinoma of rectum with reference to preservation of mechanism of, 560
- Spinal anesthesia, Epidural block, 202, effect of vasoconstrictors upon duration of, controlled study in man, 404
- Spinal cord, Neurological surgery through years of World War II, collective review, 1, effect of injury to, and cauda equina on sexual potency of men, 151, tumors of, 229, end results of operations for intrathecal extramedullary spinal tumors, with report of 9 patients whose tumors were removed 14 to 22 years previously, 229, considerations based on statistical study of surgery of, 113 observations, 229, cause of paralysis of, with special attention to factors responsible for compression, 439
- Spine, Hypertensive syndromes due to craniovertebral malformations, clinical, radiologic, and neurosurgical observations, 34, hypobaric pontocaine spinal anesthesia for exploration for extruded nucleus pulposus, 201, certain observations on prolapse of intervertebral disc in lumbosacral assimilation of vertebrae, 285, vertebral angiography, 345, late paralysis of, after avulsion of brachial plexus, 346, poliomyelitic scoliosis, 497, plain radiography in intraspinal protrusion of lumbar intervertebral discs, correlation with operative findings, 511, intervertebral disc hernias of cervical region, 541, contribution to question of origin of anterior paradiscal defects and so-called persisting apophyses in vertebral bodies, 593, recent advantages in roentgen diagnosis of pathologic conditions of, 605
- Spleen, Frontiers of Banti's disease, 208, venous block of, and splenomegaly inhibition of bone marrow, 258, irradiation of, 376, present concepts in surgery of, 467

SUBJECT INDEX—ABSTRACTS—VOLUME 89

Splenectomy, On, with reference to indications, 62, in
Brucella infection, 63, primary splenic neutropenia,
specific indication for, 174, role of, in thrombopenic
purpura, 372, fever following, 372, indications and re-
sults of, 562, value of, in splenomegalies caused by ma-
laria, 564, combined, and protacaval shunts in portal
hypertension, 564
Splenomegaly, Splenic arteriovenous anastomosis, and
Banti's disease, 62
Stellate ganglia, Sequelae of electrocution and infiltration of,
396

Sterility in Finnish women with reference to causes and
prognosis, 68
Sterilization of plaster bandages, 310
Sternum, Recent studies of multiple myeloma, puncture of,
and ribs, and results of treatment with stilbamidine,
284

Stilbamidine, Recent studies of multiple myeloma, sternal
and rib puncture and results of treatment with, 284
Stomach, Ulcer of, study of 600 cases, 49, subcardiac ulcer
of, 50, gastrojejunal ulceration, 51, partial gastrec-
tomy for peptic ulcer, 51, polyps of, 52, end results in
treatment of cancer of, 53, control of secretion of, 161,
histologic basis for anacidity in disease of, 161, man-
agement of massive gastroduodenal hemorrhage, 162,
gastrojejuno-colic fistula, 163, new problems in treatment of
duodenal ulcers, 164, surgical methods in treatment of
gastroduodenal ulcers, 164, surgical methods in treat-
ment of gastroduodenal ulcers, 164, partial gastrec-
tomy for peptic ulcer, 164, neurogenic tumors of, 165,
distribution of gastric changes accompanying gastric
cancers in various locations, 166, on 1,000 cases of re-
sected, 167, roentgenologic deformities of pyloric por-
tion of, with absence of surgical and pathologic find-
ings, 204, pseudoulcerative gastritis, 244, hypertrophy
of pylorus in an adult, with massive eosinophil infiltra-
tion and giant cell reaction, 244, diagnosis of gastric
neoplasms, 245, benign tumors of, case of lipoma and
mucosa ventriculi simulating cancer of, 245, immediate
ism of postgastrectomy syndrome, 246, immediate and
late results in treatment of perforated gastroduodenal
ulcer, 246, experimental research on behavior of duo-
denal stump following exclusion resection, 247, roent-
genologic symptoms of injuries of esophagus and, re-
sulting from caustic poisons, 303, dyskinesia of, roent-
gen kymographic semeiology, 304, analysis of x ray
findings in 405 cases of benign ulcer of, and pylorus,
304, vascularization of human, preliminary note on
shunting effect of trauma, 362, acute perforations of,
and small bowel ulcerations, 362, diverticula of, report
of 30 cases and review of literature, 363, surgical treat-
ment of peptic ulcer in region of cardia, 363, produc-
tion of gastric and duodenal ulcers by prolonged ad-
ministration of mecholy, 363, total gastrectomy, 364,
malfunction of gastrojejunal anastomosis during early
postoperative period following gastrectomy, 365, de-
tection of gastric carcinoma by photofluorographic
methods, introduction, equipment, and design, 407,
vascularization of human, 456, ulcer of, 457, on opera-
tive treatment of gastric and duodenal ulcer at District
Hospital Hämmeenlinna, Finland, 458, benign nonepi-
thelial tumors of, 458, on linitis plastica and on scleros-
ing carcinoma of, (carcinoma disseminatum Krom-
pecher carcinoma fibrosum Konjetzny), 459, clinical
notes, 3 cases of cancer of, cured by resection, 459, pre-
liminary report on advantages of small stoma in par-
ietal gastrectomy for ulcer 460, 2 cases of persistent
jejunitis following partial gastrectomy, 461, diagnosis
of congenital obstruction of, and small intestine in

newborn, 514, surgical treatment of carcinomas of dis-
tal three-quarters of thoracic esophagus and cardia,
548, new operation for gastropnoia, 551, fate of pa-
tients following operations on, 552, on acute pancreatic
affections following gastric resections for ulcer or can-
cer, and possibilities of avoiding them, 562, accuracy of
roentgen diagnosis of benign gastric ulcer, 603, roent-
genologic studies of abdominal aorta in individuals
over 50 years of age as aid to differential diagnosis be-
tween benign and malignant ulceration of, 603

Strabismus, Horizontal concomitant, 141
Streptomycin, And surgery in anorectal tuberculosis, 58,
preliminary results of therapy with, in tuberculosis of
peritoneal cavity and of adnexa in female, 68, use of, in
pulmonary resections, 156, appraisal of oral, as in
intestinal antiseptic, with observations on rapid devel-
opment of resistance of *Escherichia coli* to, 167, treat-
ment of urinary and genital tuberculosis with, 190, ef-
fects of, on eighth nerve system, 208, tuberculosis of
ear, nose, and throat treated with, report of 12 cases,
222, in urogenital infections, 279, as adjunct in surgical
treatment of pulmonary tuberculosis, 352, role of, in
surgery of pulmonary tuberculosis, 352, evaluation of,
as protective agent in pulmonary resection for tuber-
culosis, 353, experimental and clinical studies of role of,
in pleural cavity, 355, in surgical patients, 355, in
nontuberculous urinary infections, 494, in surgical in-
fections, nonpulmonary tuberculosis (lymph nodes,
urinary tract, bone, and peritoneum), 509, in urogenital
tuberculosis, 585, in nontuberculous infections, 599
Sulfonamides, Study of vehicles and adjuvants for, and
penicillin, 599

Suppuration, Treatment of, of hip joint following injuries
by firearms, 291
Sutures, Abdominal wound closure in substandard patient,
47, critical and experimental studies of, of colon in
dogs, 559
Sympathicoblastoma, Pararenal, in children under 5 years
of age, 271

TACHYCARDIA in children during anesthesia, 301
Tamponade, Aspiration of blood from pericardium in
treatment of acute cardiac, after injury, further experi-
ence, with report of cases, 450
Tantalum, Experimental production of gradual occlusion
of large arteries with polythene and, 500
Temporomandibular joint, Contribution to study of con-
genital ankylosis of, 223
Tendons, Rupture of Achilles, 287, discussion of repair of,
293, ruptures of muscles and, 496, transfers of, and
arthrodeses in combined median and ulnar nerve
paralysis, 589
Tenosynovitis of extensor carpi ulnaris tendon sheath, 87
Teratoma, Testicular tumors, seminoma and, 84, malig-
Testicles, Tumors of, seminoma and teratoma, 84, malig-
nancy in cryptorchidism, 584
Testosterone propionate in treatment of breast cancer, 543
Tests, Provocative, in glaucoma, 29, pressor, for glaucoma,
30
Tetanus, Treatment of, 97, plaster of paris as source of in-
fection in, and gas gangrene, 207, recurrent, 598,
treated as respiratory problem, 598
Tetraethyl pyrophosphate, Miotic and antiglaucomatous
activity of, in human eyes, 145
Thoracic duct, Notes on anatomy and physiology of, and
on treatment of injuries to it, 297
Thoracoplasty, Anesthesia for, use of pentothal curare
mixture supplemented with nitrous oxide oxygen, pre-
liminary reports, 201, in treatment of giant tuberculous

INTERNATIONAL ABSTRACTS OF SURGERY

- caverns, 235, stratigraphy in 1947 and in 1930 from initiation to termination of, 303
- Thoracotomy, Exploratory, 17 pleural empyema 242
- Thorax, Rupture of bronchus due to external chest trauma, report of 3 cases with recovery, 38, traumatic bronchial ruptures with occlusion, 39, constrictive pericarditis and physiology of coarctation of aorta, 43, traumatic chylothorax, 45, traumatic chylothorax, 150, right thoracoabdominal approach, 160, covering of lattice lung and residual apical pleural cavity by transplantation of tubed pedicle flap, 238, indications for pulmonary resection with reference to extent of operation 238, neurofibroma, 240, notes on anatomy and physiology of duct of, and on treatment of injuries to it, 297, anesthetic management for surgery within, report of 300 cases, 299, clinical considerations on case of tumor of upper lobe of right lung (Pancoast's syndrome) with secondary infection, diffusion of process to right supraclavicular and laterocervical region and subsequent fistulization, 354, thymoma, 359, operative treatment of pectus excavatum, 442, statistical contribution to subject of surgery of mediastinum, 451, bodies, 452, differential diagnosis of hiatus hernia and coronary artery disease, 453, pyogenic empyema and extension below diaphragm, 544, operative handling of aortic coarctation, 456, surgical treatment of megadolichocephalus, esophagogastronomy of necessity or on principle? 547
- Thorotrast, Studies on harmful effects of, on tissue, 306, concerning injuries from, and sarcoma peril of, 306, should we continue to use, for angiographic purposes? 307, programs with, in cerebral abscess, 342
- Throat, Antibiotics in treatment of diseases of ear, nose and, 534
- Thromboangitis, Histopathologic contribution to our knowledge of Buerger's disease (obliterating), 199
- Thromboembolism, Attempt to evaluate different modern methods for prevention and treatment of, 94
- Thrombosis, Management of venous, and pulmonary embolism following injury to extremities, 93, unexplained, of internal carotid artery, 199, venous, and anticoagulants, 501
- Thumb, Treatment of open traumatism of hand in miners 95
- Thymectomy, In treatment of myasthenia gravis, report based on 32 cases, 550
- Thymolipoma, Case of, 350
- Thymoma, 359
- Thymus gland, Comparison of hyperplasia of, in myasthenia gravis and exophthalmic goiter 358
- Thyroid gland, Frequency of hyperthyroidism, causes and therapy, 32, radioactive iodine as diagnostic aid for intrathoracic goiter, 102, foreign body in, following perforation of esophagus, 224, observations on disorders of, associated with exposure of suprarenal glands to x rays, 225, contribution on 564 goiters and 543 goiter operations performed in 1946 340 nontoxic nodular goiters, 437, carcinoma of, 438 anesthesia for surgery of, 601
- Thyroiditis, Clinical aspects of chronic, 32
- Thyroidosis, Treatment of, 33, treatment of, 147 surgical treatment of 226 treatment of 536
- Tibia, Ischemic necrosis of anterior muscles of, 286 conservative therapy of agenesis of and fibula, report of 5 clinical cases 405 metallic osteosynthesis with medullary graft for pseudarthrosis of tibia 405
- Toes, Removal of base of proximal phalanx in hallux rigidus 591
- Tongue, Irradiation in cancer of, 100, indications for anesthesia and mode of introduction of anesthesia for cancer of, 201, some rare benign tumors of 21
- Tonsil, Clinical and pathologic study of tags of, 437
- Torticollis Spasmodic surgical treatment, 496
- Trachea, Amyloid tumors of larynx, bronchi, or, report of 15 cases, 538
- Trauma, Clinical assessment of peripheral nerve injuries, 35, condition of abdomen due to, 63, evaluation of principles concerned in management of, to kidney, 313
- Trigeminal nerves, Tractotomy, observations on 48 cases 344
- Trochanter, Tuberculosis of greater, and bursa of, 50
- Tuberculosis, Studies in experimental ocular, effect of promin and promizole on experimental ocular, in immune allergic rabbit, 27, streptomycin and surgery in anorectal, 58, preliminary results of streptomycin therapy in, of peritoneal cavity and of adnexa in female, 68, urinary, 85, decortication of non-expandable postpneumothorax lung, with, 155, use of streptomycin in resection for pulmonary, 156, condition of bladder and ureters after nephrectomy for renal, 158, treatment of urinary and genital, with streptomycin, 100, studies in experimental ocular, effect of promin and promizole in experimental ocular, in normal rabbit 217, of ear, nose and throat treated with streptomycin report of 12 cases, 222, thoracoplasty in treatment of giant caverns due to, 235, remaining kidney in cystitis due to, after nephrectomy, 271, of greater trochanter and trochanteric bursa, 286, diagnosis of internal genital, in male by roentgenograms, 305, streptomycin as an adjunct in surgical treatment of pulmonary, 15 evaluation of streptomycin in surgery of pulmonary, 352, monary resection for, 353, comparison of results in 200 consecutive resections for pulmonary, 353 streptomycin in surgical patients, 355 esophagocystic urinary, 385, surgical treatment of osteoarthritic experimental studies on pathogenesis and treatment of ocular, 478 tracheobronchial, in general and its connection with pulmonary surgery, 443 streptomycin in surgical infections, nonpulmonary, (lymph nodes, urinary tract, bone, and peritoneum), 509, surgical extra pleural pneumothorax in treatment of large cavities due to, at upper lobe of lung 543, case of gall bladder 561, contribution to study of reports of pulmonary and pregnancy, 575, streptomycin in urogenital, 585, indications and results of management of joint, 586
- Tumors, Delays and errors in diagnosis of brain, 31, probability of solitary lung 39 report of 2 cases of, of internal theca of ovary 65, of kidney, 79, attempt at classification of bladder, 81, diagnosis and therapeutic indications in, of bladder, 82, testicular, seminoma and teratoma, 84, spindle cell, of gastrointestinal tract, 101, colonic and proctologic diverse collective review 105, epithelial, associated with developmental cysts of maxilla, 141, neurogenic, of stomach, 165 malignant of colon and rectum, 170, concerning 2 cases of Krunkenberg 178, torsion of organs and of, of female primary bladder, 188, giant cell, of sacrum, case report 192, some rare benign, of tongue, 221 prognostic criteria and therapeutic suggestions for treatment of, of pharynx 224, absence of headaches in certain type of frontal lobe 227 of spinal cord 29 and result of operations for intrathecal extramedullary spinal with report of 9 patients who were removed 11 to 2 years previously, 29 refinement of technique in cyst,

logic diagnosis of, of bronchus, 237, diagnosis of gastric, 245, benign, of stomach, case of lipoma sub mucosa ventriculi simulating cancer of stomach, 245, of optic nerve, long survival in 3 cases of intracranial, 336, chemosurgical treatment of, of parotid gland, 339, tuberosus sclerosus with cerebral, 343, of acoustic nerve, clinicosurgical considerations of 250 cases, 344, clinical considerations on case of, of upper lobe of right lung (Pancoast's syndrome) with secondary infection, diffusion of process to right supraclavicular and latero-cervical region and subsequent fistulization, 354, argentaffine, of gastrointestinal tract, report of 11 cases, 361, dystocia due to obstructing, 377, treatment of papillary, of ureter, 383, cancer problem, 415, of Kuttner, 436, benign nonepithelial, of stomach, 458, malignant, of small intestine, 461, limitation and extension of syndrome of Demons-Meigs, 472, 2 cases of benign connective tissue, of female external genitalia, 473, classification of kidney, 487, of ureter, 489, essential bone cysts and giant celled bone, 495, primary hemangioma of skull, rare cranial, 511, ovarian, in pregnancy, collective review, 525, amyloid, of larynx, trachea, or bronchi, report of 15 cases, 538, multiple brain, 539, analysis of electroencephalographic findings in 40 cases of varied brain, electroencephalographic findings in meningiomas, 540, hyperfunctioning, of adrenal cortex, with report of 8 cases, 577, consideration of paranephritic, 579, problem of perirenal or capsular, of kidney, 581, of renal pelvis, 581, biopsy and end results of bladder, 582, multiple lipoma-angiolipomas, 610

ULCERS, Gastric, study of 600 cases, 40, subcardiac gastric, 50, gastropyloric, 51, partial gastrectomy for peptic, 51, palliative gastrectomy in cases of duodenal, 52, surgery of complications of colitis, 57, etiology of leg, and their treatment by resection of popliteal vein, 92, preliminary note on treatment of hypopyon, with crystalline penicillin in adrenalin in doses exceeding 50,000 units injected by subconjunctival or retrobulbar routes, 145, management of massive gastroduodenal hemorrhage, 162, new problems in origin of gastric, 163, surgical methods in treatment of gastroduodenal, 164, surgical methods in treatment of gastroduodenal, 164, partial gastrectomy for peptic, 164, etiology of chronic colitis with, 170, surgical treatment of non specific colitis with, 170, surgical treatment of chronic colitis with, 170, immediate and late results in treatment of perforated gastroduodenal, 246, colitis with, 249, idiopathic colitis with, 250, further consideration of surgical management of chronic varicose, 296, analysis of x ray findings in 405 cases of benign gastric and pyloric, 304, tropical phagedenic, problem of phagedenic, 311, hematemesis 361, acute perforations of stomach, and, of small bowel, 362, surgical treatment of peptic, in region of cardia, 363, production of gastric and duodenal, by prolonged administration of mecholyl, 363, surgical therapy of duodenal 366, some observations of Curling's, 403, gastric, 457, on operative treatment of gastric and duodenal at District Hospital Hämeenlinna, Finland, 458, preliminary report on advantages of small stoma in partial gastrectomy for, 460, management of bleeding duodenal, 461, development of deep duodenal, 552, treatment of jejunal comparative follow up study, 553, present concepts in colitis with, 554, colitis with ileostomy life, 555, colitis with clinical features, diagnosis, and treatment 556 accuracy of roentgen diagnosis of benign gastric 603

Umbilicus, Healing and infections of, 185
 Urachus, Tumor and superimposed cyst of, 86, cancer of, 86
 Urecholine, Gastrointestinal motility following vagotomy and use of, for control of certain undesirable phenomena, 54
 Ureter, Megaloureter, report of 2 cases, 186, diverticulum of, 186, implantation of secondaries from renal carcinoma (hypernephroma) within lumen of, 186, new method of implantation of, into urinary bladder, 187, results in intestinal anastomosis with, 187, condition of bladder and, after nephrectomy for renal tuberculosis, 188, double formations of pelvis of kidney and, embryology, occurrence, and clinical significance, 270, treatment of papillary tumors of, 383, carcinoma of, 383, transureteropyelostomy and transureteroureterostomy, 383, gynecologist, urologist, and, 475, etiological and therapeutic experiences concerning stones in kidney and, 487, congenital stenosis of, at origin, 488, tumors of, 489, technique and results of anastomosis between, and colon by extraperitoneal route, 489, transplantation of, 489, morphological and functional significance of sheath of, and so-called fissure of Waldeyer, 493
 Ureterostomy, Pedicle graft cutaneous, 489
 Urethra, Diverticulum of, in female, clinical study, 476, resection of, for neurogenic bladder, 490, primary carcinoma of male, 491, female, 492, radium therapy in carcinoma of female, 608
 Urinary function, Neurological surgery through years of World War II, collective review, 1
 Urinary tract, Studies on back flow in excretion urography, 76, intravenous urography and retrograde pyelography in subcutaneous injuries of kidney, 78, uroterointestinal implantation and total cystectomy for cancer, 80, neuromuscular dysfunction of, 85, tumor and superimposed cyst of urachus, 86, cancer of urachus, 86, diverticulum of ureter, 186, incontinence of urine caused by dysplasia of vesical neck, with paradoxical vesicoureteral reflux, nephroureterectomy and Young's operation, classification of urinary incontinence, 190, cause of hematuria, 272, an evaluation of antiseptic drugs and antibiotics in treatment of infections of, 278, fistula between rectum and, 280, transureteropyelostomy and transureteroureterostomy, 383, congenital stenosis of ureter at origin, 488, transplantation of ureter, 489, female urethra, 492, orphological and functional significance of ureteral sheath and so called fissure of Waldeyer, 493, streptococci in nontuberculous infections of, 494, consideration of paranephritic tumors, 570, calculi of, 585
 Urine, Device for obstructing flow of, in intravenous urography, 270, experimental contribution to study of chloridemia in rabbits with puncture of chloride center, 493
 Urography, Device for obstructing urinary flow in intravenous, 270, evaluation of principles concerned in management of trauma to kidney, 313
 Urologist, Ureter, gynecologist, and 475
 Urology, Considerations on subject of anesthesia in, 281
 Uterine tubes, Primary carcinoma of, clinical and pathologic study with personal contributions, 66, diagnosis of pregnancy in, 571
 Uterus, Problem of presence of sensitive corpuscles of, 65, radiologic diagnosis of cancer of, 65, possibility of venous embolism in course of hysterocalpangography, 69, newer methods in management of abnormal cervix, 175, vaginal cytology in cancer of, 175, adenocarcinoma of, 175, adenocarcinoma of cervix and of cervical stump, 176, carcinoma of cervix 176, present day status of noninvasive cervical carcinoma, 176 contro-

versal factors in management of carcinoma of cervix, 177, desirable management of fundal carcinoma, 177, role of surgery in treatment of carcinoma of cervix, 178, leiomyosarcoma of, 178, roentgenogram in malformation of, with respect to function, 260, wide conization of cervix, 260, malignant tumors of fundus of, subsequent to irradiation for benign pelvic conditions, 260, cancer of cervix of, 260, value of postoperative irradiations of cancer of, 261, modifications of rectal mucosa in cancer of cervix of, 263, intravaginal roentgen therapy in cancer of cervix of, 308, review of 10 years experience with transvaginal roentgen therapy, 308, immediate and late results of intracavitary radium therapy for malignant lesions of cervix, 309, carcinoma of cervical stump, 309, visualization and photography of canal of, 374, clinical signs of adenocarcinoma of cervix of, 374, fibromyxochondrosarcoma of cervix of, 374, role of surgery in treatment of carcinoma of cervix of, 374, discussion of certain findings at autopsies of patients with cancer of, 375, surgical indication of hysterectomy with castration in hydatidiform mole, 375, medical treatment of inertia of, 377, obstetrical rupture of, in Finland during years 1936 to 1943, especially from point of preventive and clinical treatment, 378, place of deep external x-ray irradiation in treatment of carcinoma of cervix by long element needles, 411, probable trends in irradiation treatment of carcinoma of cervix of, with improved expanding type of radium applicator, 411, doubtful malignant changes in endometrial epithelium, report on 60 cases from Radiumhemmet, 469, surgical treatment of endometriosis, 469, complication of endometriosis, 469, 4 new cases of malignant neoplasm on cervical stump, 470, unsuspected cervical cancer in gynecological patients, 470, results of treatment of carcinoma of cervix of, (1936-1941), 471, Wertheim's operation in retrospect, 471, carcinoma of cervix, 1948 survey of treatment in United States and Canada, collective review, 521, roentgenogram of, with respect to function with exclusion of malformations, 567, clinical classification of carcinoma of endometrium, 567, late results of Revoltella's anterior hysteroidoligamentopexy, 568, physiopathology of contraction of, 573, reactions to x ray and radium therapy in treatment of cancer of cervix of, 607

VAGINA, Two cases of atresia of, observed in duplex anomalies of genitalia, 67, significance of abnormal menopausal smears of, 263, remarks on pathologic physiology of endometrioses on occasion of 3 observations of endometriosis of posterior vault of, 567

Vagotomy, Physiological aspects of, 53, gastrointestinal motility following, and use of urecholine for control of certain undesirable phenomena, 54, x ray observations before and after, 305

Varices, On treatment of, by ligation of saphenous vein and injection in both central and peripheral directions according to Ollonqvist's method, 92, phlebography and surgery of true, in veins of lower limb, 295, treatment of, of lower extremities, 296, further consideration of surgical management of chronic ulcers due to, 296, op-

eration for severe, in veins during pregnancy, 479, syndrome of arterial, 500

Varicocele, 583, technique of operation of Furico Branco Ribeiro, 277

Veins, On treatment of varicose, by ligation of saphenous, and injection in both central and peripheral directions according to Ollonqvist's method, 92, etiology of leg ulcers and their treatment by resection of popliteal, 92, management of thrombosis of, and pulmonary embolism following injury to extremities 93, evaluation of phlebography of normal lower extremity, 99, phlebography and surgery of true varicose, of lower limb, 295, postphlebitis sequelae, 393, operation for severe varicose, during pregnancy, 479

Vena cava, Injury of, during nephrectomy, 79, obstruction of superior, review of literature and report of 2 personal cases, 594

Vitamins, Ménière's syndrome, observations on deficiency of, as causative factor, vestibular disturbance, 336

Vitreous, Use of pooled human, 219

Vocal cords, Reverse King operation, surgical procedure for restoration of phonation in cases of aphonia due to unilateral paralysis of, 341

Volkmann's contracture, Fundamental concepts in treatment of completely arrested, 592

Vulva, Carcinoma of, 474, Bowen's disease of, 568

WAR, Neurological surgery through years of second World, collective review, 1, abortions, premature births, and weight of newly born during period of, 379, wounds of extremities, 397, study of penetrating wounds of abdomen in Finnish fighting forces during, of 1941-44, 565

Water test, Provocative, in glaucoma, 29, response of gall bladder to Benassi-Vitale's, in course of cholecystography after gastric resection, 604

Wertheim's operation in retrospect, 471

Wirsung's canal, Reflux into, in course of cholangiography, dystonia of, 60

Wounds, Neurological surgery through years of World War II, collective review, 1, experimental study of healing of, new technique and study of effect of detergents and of antacid on healing of, 206, effect of injury on healing of, 311, of colon and rectum, critical analysis of current methods of surgical treatment with emphasis on details of surgical technique, 368, of extremities, 397, open, of brachial plexus, 440, injuries and death from lightning, 504, treatment of burns, 504, management of severe burns, 505, rapid elimination of eschar of burns by use of pyruvic acid, 508, bacitracin in surgical infections of, 510, study of penetrating war, of abdomen in Finnish fighting forces during war of 1941-44, 565, healing of, as biologic phenomenon, 609

Wrist, End results of excision of carpal bones, 195, arthrodesis of, by technique of Smith and Petersen, 287, treatment of fractures of metacarpals, 290, follow up results of surgical treatment for nonunion of carpal scaphoid bone, report of 19 cases, 391, fundamental concepts in treatment of completely arrested Volkmann's contracture, 592
